Velen hebben bijgedragen aan de totstandkoming van dit proefschrift. In het bijzonder wil ik bedanken

Dr. S. Stolte en Drs. A. Zandee voor de vele verhelderende discussies.

De Heren Drs. A. van Lumig en M. Waaijer voor de medewerking tijdens hun afstudeerperiode.

De Heren C. Sikkens, F. van Rijn en L. Hendriks voor hun hulp op technisch en electronisch gebied.

De dienstverlenende afdelingen, in de persoon van de Heren J. G. M. van Langen, P. C. Walraven en H. Verschoor, voor het vervaardigen van de vele onderdelen van de apparatuur en de Heer H. W. Boltze voor de stroom van vloeibare gassen.

Mej. L. v. Doorn voor het vele typewerk aan het manuscript.

De figuren en omslag zijn vervaardigd door de afdeling illustratie onder leiding van de Heer J. Gerritsen.

Het artistiek beeld van de opstelling is van de hand van de Heer L. Hendriks.

Het onderzoek, beschreven in dit proefschrift maakt deel uit van het programma van de stichting Fundamenteel Onderzoek der Materie en is mogelijk gemaakt door de financiële steun van de "Nederlandse Organisatie voor Zuiver Wetenschappelijk Onderzoek (Z.W.O.)".

I INTRODUCTION

I.1. INTRODUCTION

In the beginning of this century the molecular beam technique was introduced. Molecules effuse from a source into vacuum through a small orifice. With the aid of diaphragms a minute fraction of all effusing molecules is selected to form a beam of non-interacting molecules; this beam is used for further experiments, among others the famous Stern Gerlach experiment.

In the source the pressure is held such that $d/\lambda \leq 1$; λ stands for the mean free path of the molecules in the source, d is the orifice diameter. Optimum intensity of the beam is reached for $d/\lambda = 1$

At higher pressures the intensity levels off and the source becomes diffuse, due to the supposed formation of a cloud in front of the source; this cloud would limit the intensity, functioning as a broad virtual source. Formation of the cloud is considered uninfluenced by the pump capacity; its origin is attributed to collisions of effusing beam molecules amongst themselves.

In 1927 Johnson reports a continuous intensity increase for an Hg-beam, up to pressures at which $d/\lambda \simeq 1000$. The first chamber of his apparatus is pumped with a liquid air trap, a more effective pump for Hg than possible for any other gas at that moment. He attributes the intensity limitation of earlier experiments to a pressure build up in the first chamber by insufficient pumping. His experiment, however, fails to draw appropriate attention.

Some years later, Rodebush proposes a source design with a conical first diaphragm (skimmer) to avoid the cloud formation. His design, very similar to a modern nozzle source, is ignored for a long time, too. Sources are operated at $d/\lambda \simeq 1$, and the spurious cloud continues to obscure the truth.

It is 1951 when Kantrowitz and Grey propose a high pressure source, using flow conditions which can be described by continuum theory. In their design the gas is allowed to expand freely from high pressure into vacuum through a nozzle. Thereby, the thermal energy of the gas is converted into flow energy in forward direction. Orders of magnitude were promised to be gained in intensity if the $d/\lambda = 1$ barrier would be left behind. A skimmer cuts the central part out of the flow, which is transferred to high vacuum and forms a molecular beam. In 1951 a first attempt by Kistiakowsky and Slichter does not yet fulfill all expectations, although they demonstrate that higher intensities can be obtained. In 1954, Becker and Bier are able to observe the predicted increase in intensity and narrowing of velocities with the aid of larger pumps. Since then the development and understanding grows rapidly. To illustrate this, a time table is given below.

- 1911 Dunoyer, design of first molecular beam apparatus (*Le Radium*, 8, 142)
- 1919 Stern and coworkers, start of a series of beam experiments (*Z. Physik*, 2, 49 and 3, 417)
- 1926 birth of the "cloud" (*Z. Physik*, 39, 764 and 780)
- 1927 Johnson, first free jet source, unrecognized attack on the cloud (*Phys. Rev.*, 31, 103)
- 1931 Rodebush, review of the early experiments of Stern; proposal of a source design similar to modern nozzle source (*Rev. Mod. Phys.*, 3, 392)
- 1951 Kantrowitz and Grey, proposal of a continuous flow source (*Rev. Sci. Instr.*, 22, 328)
- 1951 Kistiakowsky and Slichter, first attempt with a nozzle source (*Rev. Sci. Instr.*, 22, 333)
- 1954 Becker and Bier, investigation of beams with Laval nozzle shows predicted high intensity and narrow velocity distribution. Discovery of beam seeding (N_2 in H_2) (*Z. Naturforschung*, 9A, 975)
- 1956 Becker et al., sudden discontinuity in velocity distribution and increase in beam intensity at high pressures. First suggestion of condensation in the beam (*Z. Physik*, 146, 333)
- 1958 First rarefied gas dynamics symposium (Nice)
- 1961 Bentley et al.; Henkes et al., independent reports of condensation in highly expanded nozzle beams, detection of small clusters by a mass spectrometer (*Instruments and Measurements*, 5th Conference, Stockholm; *Z. Naturforschung*, 16A, 842)
- 1966 Andres, Anderson and Fenn, investigation of jets from nozzles, determination of velocity distribution in molecular beam. A study of the transition of continuum flow to free molecular flow. Velocity slip and seeding of gas mixture expanding from nozzle studied. (see J.B. Anderson in "Molecular Beams and Low Density Gasdynamics", ed. P. Wegener, M. Dekker, New York)
- 1966 McMichael and French, electron beam fluorescence for density measurements in the beam (*Phys. Fluids*, 9, 1419)
- 1967 Marrone, electron beam fluorescence to determine temperature (rotational) and density in the expansion (*Univ. of Toronto. Inst. Aerosp. Studies, Rep. no 113*)
- 1969 Andres and Miller, a two dimensional Maxwell Boltzmann model to deal with the non-isotropic character of the flow for mixtures of gases (VIth RGD symposium)

Experiments with the techniques mentioned above and those in large scale wind tunnels have led to a good understanding of the flow from the nozzle orifice and the transition from continuous flow to free molecular flow. Some recent molecular nozzle beam experiments worthwhile to be mentioned (IXth. R.G.D., Göttingen) are

- 1974 Campargue, alternative pumping system, able to produce the beams with speed ratios $v/\Delta v$ exceeding 150
 - 1974 Malthan and Toennies, cooling of CsF by seeding with Xe, achieved rotational temperature of 20K
 - 1974 Winkelmann and Toennies, application of Miller-Andres theory for pure gases with quantum mechanical collision cross sections
 - 1974 Lewis et al., rotational distribution of N_2 in nozzle beams measured by electron beam fluorescence and laser (Raman) scattering.
- Since its discovery in 1956, condensation in beams from small nozzles has had the attention of a considerable number of investigators.
- 1960 Becker et al., start of a series of experiments by Henkes, Hagena and Gspann and others on beams with clusters containing up to 10^6 molecules. Cluster beams of He are produced. Cluster beams of hydrogen isotopes are proposed for thermonuclear reactions. Also studied are mass separation effects. (†)

Alkali dimers can be separated from monomers and trimers by deflection in an inhomogeneous magnetic field. In reactive scattering one can distinguish between monomers and dimers by the different kinematics. Klemperer and Muentert are able to discriminate dimers vs. larger clusters by the use of focusing fields. For atoms or molecules which have no magnetic or electric dipole moment we have to look for other characteristics, by which clusters of different size can be recognized. In most experiments involving clusters of noble gases or simple diatomics only a mass spectrometer has been used for detection. Little is known about the fragmentation which may occur in the ionization process. Due to lack of information fragmentation is often neglected completely.

1.2 NEW INFORMATION, DESCRIPTION OF THE CONTENTS OF THIS THESIS

In the experiments described in this thesis a nozzle beam is detected by a mass spectrometer; the intensity of signals for ion masses four times the monomer mass or more is measured as a function of the source pressure P_0 at certain fixed temperatures T_0 .

In chapter II which has been published in 1973, the first results are given for an H_2 -cluster beam. The intensity of the ion signals and the velocity of the corresponding neutral clusters have been measured. At low pressures the dimer signal is masked by a space charge in the ionizer, which produces spurious dimer ion signals. With the ionizer tuned to work without space charge pure dimer signals are detected.

In chapter III, published in 1975, the intensities and cross sections for Ar-clusters are communicated; in chapter IV those for Ne, H_2 , N_2 , NO and O_2 . With increasing source pressure P_0 all cluster ion signals appear in order of increasing mass number, m ; they show a rise proportional to $P_0^{\alpha_m}$. The pressure region where this proportionality holds is called the onset region. At pressures above the onset region the signals go through a maximum. Because α_m is found to be independent of the source temperature T_0 , the pressures can be scaled such that the ion intensities of each species coincide for different T_0 . This reduction of quite a body of observational material into simple empirical plots (see fig. III.1 for instance) is a step forward compared to most earlier investigations, where this onset region was overlooked due to the use of less efficient detectors.

To be sure of the origin of the ion signals and to fill the information gap concerning the fragmentation in the ionizer, we have installed a collision cham-

ber in the neutral beam path and have determined the attenuation of the ion signals due to a scattergas. If an ion signal corresponds to a single cluster species, a constant attenuation is measured independent of P_0 . The important outcome of our work is that this correspondence exists for dimers and monomers in the onset region. Once this correspondence had been established, the total collision cross sections of dimers can be obtained. (see chapter III and IV).

In chapter V the results for a He-cluster beam, published in 1975, are given. Signals from He_2^+ -ions are detected. At low pressures the measurement of the total collision cross section proves that a single neutral parent is responsible for this signal; it is concluded that this parent must be a He-trimer.

For each source temperature T_0 a pressure P_1 is defined in chapter III and IV where the attenuation of the dimer ion signal starts to rise above the value which corresponds to neutral dimers. At this pressure the dimer ion signal becomes contaminated by fragments of larger clusters. Larger cluster ions appear at pressures slightly higher than P_1 . For Ar, Ne, H_2 , and N_2 the temperature dependence of P_1 has been determined. Applying the principle of corresponding states a simple empirical formula is given in section IV.4.

For dimers which may possess a sufficiently large magnetic moment - those of H_2 , NO and O_2 - we have looked for information on this moment from the deflection of the dimers in an inhomogeneous magnetic field, see section IV.5. From the deflection of $(\text{H}_2)_2$ we infer a magnetic moment comparable to that of the monomers. For $(\text{O}_2)_2$ a deflection of 70% of the beam is observed in strong fields and for $(\text{NO})_2$ no deflection at all. Consequently, for some investigators more unexpectedly than for others, free O_2 -dimers possess a magnetic moment.

At pressures lower than P_1 only dimers and monomers are present in the nozzle beam. The question arises whether the observed dimers are already present in the source (prefabricated), or are they formed during the expansion (postfabricated)? To answer this question we have compared in chapter VI the measured dimer fraction with the calculated equilibrium fraction in the source. For Ne, Ar and H_2 the observed dimer fraction is in fair accordance with these calculations over a range of dimer intensities of two orders of magnitude. The diatomic systems show a temperature dependence of the dimer fraction which fits prefabrication. However, the pressure dependence does not follow a P_0^2 - law as expected for prefabricated dimers. Together with other experimental evidence (section VII.4) this deviation has convinced us that the dimers are actually postfabricated, as discussed in section VI.4.

The investigation of cluster beams from gas mixtures is described in chapter VII. Addition of Ar to Ne, Ne to He, and Ar to H_2 leads to the production of mixed dimers, NeAr, HeNe, and H_2Ar . Their intensity has been measured as a function of P_0 and their total collision cross section determined. An increase of Ar-dimers in the Ne-Ar mixture is observed with respect to the pure Ar-case, see section VII.4.

In chapter VIII we discuss the ratio of dimer to monomer cross section, σ_2/σ_1 as a function of reduced velocity, $v_{\text{red}} = \hbar v / \epsilon R_m$. The collision velocity v has been calculated under the assumption of full isentropic expansion of the nozzle beam taking into account the thermal velocity of the scattergas. The values for ϵ and R_m are taken from a Lennard Jones 12-6 interaction potential between the monomer and the scattering partner. The important feature of this plot is that in good approximation all our dimer results fall on a single curve for a large range of v_{red} .

At low reduced velocities, $v_{\text{red}} < .4$, σ_2/σ_1 is found between 1.33 and 1.45. For these velocities the total collision cross section of the monomer is dominated by the attractive part of the interaction potential $-C_6/r^6$. Assuming that this holds for the dimer too, the ratio σ_2/σ_1 indicates that the C_6 -factor for the dimer interaction is about twice that of the monomer interaction.

At high reduced velocities $v_{\text{red}} \geq .8$, repulsive forces become of importance; the ratio σ_2/σ_1 reaches a value 1.9. A value $\sigma_2/\sigma_1 = 2$ would correspond to separate collisions of both monomer constituents of the dimer.

For an H_2 -beam and Ar as scattering partner the reduced velocity ranges from $v_{\text{red}} = .24$, well in the attraction dominated region, to $v_{\text{red}} = .58$, where one enters the transition region; a gradual increase of σ_2/σ_1 is found.

For NO the ratio σ_2/σ_1 is apparently lower than for all others species investigated. This may be caused by a dipole coupling between two NO molecules; NO is the only species used possessing an electric dipole moment, but also the only species where a weak chemical binding force could be expected.

II MEASUREMENTS OF INTENSITY AND VELOCITY DISTRIBUTION OF CLUSTERS FROM A H_2 SUPERSONIC NOZZLE BEAM

A. VAN DEURSEN AND J. REUSS

Fysisch Laboratorium, Katholieke Universiteit, Nijmegen (The Netherlands)

(First received 9 October 1972; in final form 27 December 1972)

ABSTRACT

Measurements on the production of $(H_2)_n$ clusters of small size are reported. The abundance of different clusters is found to rise to a flat maximum, at optimum source conditions for a specific cluster size. These maxima reach values of about 10 % of the H_2^+ signal without a strong tendency to decrease with increasing mass. The possibility of production of neutral cluster beams of known cluster size is discussed, which can be used in molecular beam scattering experiments.

INTRODUCTION

The aim of the reported experiment has been the production of $(H_2)_n$ clusters in a molecular beam suitable for scattering experiments. Our main interest was focused on clusters of small size, in contrast to the work of a group in Karlsruhe¹ on the formation of very large $(H_2)_n$ clusters.

The production of clusters takes place during the expansion of gas flow into vacuum from a high pressure source. The temperature of the source is held a few degrees above the condensation temperature. The decisive temperature drop takes place immediately behind the source opening (nozzle) where the effusing molecules still collide with each other and where thermal energy is transformed into directed kinetic energy of hydrodynamical flow. In this region neutral clusters are formed, their sizes depending on the source conditions.

The only way to detect clusters of known size is to use a mass spectrometer equipped with an electron bombardment ionizer. However, the observed cluster ions may originate from neutral clusters of different sizes. A way to judge the origin

* This work is part of the research program of the "Stichting voor Fundamenteel Onderzoek der Materie (F.O.M.)" and has been made possible by financial support from the "Nederlandse Organisatie voor Zuiver Wetenschappelijk Onderzoek (Z.W.O.)".

of a cluster ion is to look for the pressure dependence of the signal, for a fixed source temperature. Our results show that one can adjust the source conditions such that a well-defined neutral cluster appears as parent for cluster ions of a fixed mass.

We have also investigated, whether a difference in the velocity distribution for neutral clusters of different masses could serve as a means of determining the parentage of a cluster ion. However, the velocity distributions of the clusters were nearly independent of the ion mass.

The measured relative abundances of ions show that the signals for different ion masses are influenced by the different stabilities of the cluster ions. Even masses have intensities about 50 times smaller than odd masses. Mass 4 could not be detected with certainty. Ions of masses 9 and 15 appear to be of high stability.

APPARATUS

The molecular beam apparatus used was of conventional design. It consists of six separately pumped chambers (Fig. 1). The source chamber is pumped by a 1000 l sec⁻¹ jet pump with a water cooled baffle. Stable operation was obtained at pressures lower than 2×10^{-3} torr, with the molecular beam on. The next chamber contains a beam chopper w (30 Hz, permits phase sensitive detection) and is equipped with a 2000 l sec⁻¹ oil diffusion pump and a water cooled baffle. The pressure measured here was always less than 10^{-6} torr. The following chamber accommodates the velocity selector (slotted disc type). Between the chopper chamber and the velocity selector a separately pumped chamber can be inserted containing the scatter box, "b" for total collision cross section measurements. The velocity selector is followed by a buffer chamber and the detector chamber with ionizer and mass spectrometer. The pressure in the detector chamber is 10^{-9} torr

Fig. 1. Scheme of the apparatus. Heavy vertical lines indicate a division between separately pumped chambers. The detector utilizes half a sector field so that a carefully prepared parallel ion beam is needed (i = immersion-lens; e = Einzel-lens).

under working conditions. In Fig. 1 the dimensions of the whole apparatus are indicated.

During most of the measurements presented here the scattering chamber was removed. In the first chamber the molecular beam source *s* is mounted. The nozzle opening has a $28\ \mu$ diameter pierced into a $25\ \mu$ thick stainless steel foil by an etched molybdenum wire. The foil is held between a brass plate with a central bore of 1 mm diameter and a brass mounting base with a small rim for vacuum sealing. This base is attached to the source body, which can be cooled to about 20°K and wherein the pressure can be varied between 0.05 and 8 atm.

The source body is made of a rectangular copper piece with an 11 mm central bore into which a shaft of sintered material is crammed in good thermal contact with the walls. The hydrogen gas flows through this sintered material accommodating to the temperature of the source body. The whole source system is mounted onto a Klipping-He-cryostat (Leybold VMK 500). Two vapour pressure thermometers monitor the temperature of the cryostat and the source body. Between the two points a temperature difference was observed which depends on the inlet pressure; at high inlet pressures the background pressure in the source chamber increases and causes higher thermal losses.

The temperature of the source was regulated between 20° and 28°K ; most measurements were made at 26°K . Hydrogen molecules of the background gas in the source chamber intermittently condense on the capillary through which the liquid He flows to the cryostat. Consequently, the pressure in the source chamber fluctuates and causes a varying attenuation of the molecular beam. We sealed all openings between the cold capillary and the source chamber with tape and were able to reduce the beam fluctuations below a tolerable limit. A conical skimmer *sk* (90° full cone angle, 0.72 mm diameter orifice) is placed 12 mm downstream from the nozzle. The skimmer forms the only vacuum connection between the first and the second vacuum chamber. Collimation of the molecular beam is achieved by two adjustable slits *sl*, one between the chopper chamber and the scattering chamber and one in front of the detector chamber.

The molecular beam is analysed with a small magnetic mass spectrometer developed by Stolte². Its mass range is 1–40, its resolution $M/\Delta M = 40$. In the ionizer electrons of 100 eV traverse the neutral beam path. Care must be taken that the neutral beam nowhere hits the walls of the ionizer. Otherwise neutral clusters could break up and the relative values of the ion intensity at different masses would become less meaningful. The ions are detected after amplification by an open multiplier system with the conventional lock-in technique.

The gas inlet system contains two liquid nitrogen cooled traps in order to purify the source gas sufficiently. We use 96 % pure hydrogen gas which passes through the first trap whereby moisture is removed. In the second trap, which is filled with molecular sieve, the remaining nitrogen is removed. Stable operation of the nozzle is possible for more than 8 hours without clogging up.

The measurements reported in this section were all performed with the source at 26 °K. Preliminary measurements had shown that with this source temperature we got all small clusters within a convenient range of source pressures. With the source at nitrogen temperatures we were only able to detect mass 3 and mass 5 ions, the latter ones barely.

Fig. 2. Ion intensity plotted against inlet pressure. $-\cdots-$ corresponds to mass 2; $-----$ to mass 3; $--- --$ to mass 5 and 6; $————$ to mass 7 and 8; $———$ to mass 9 and 10; $-+-$ to mass 11; $-----$ to mass 13 and $-\cdots-$ to mass 15. $\cdots\cdots$ gives the dependence of the pressure in the source chamber on the inlet pressure (scale at the right).

The intensity of the ion clusters was measured as a function of the source pressure. In Fig. 2 results are shown for p_{source} between 40 and 600 torr. For reference the H_2^+ signal is shown, too. The odd masses reach intensities of about 13 % of the H_2^+ intensities, in contrast to 0.3 % for the even masses. For pressures higher than 600 torr we observed a small decrease of intensity for small clusters while the H_2^+ signal still rose. However, at these high pressures the background pressure in the source chamber rises to about 10^{-3} torr and strongly interferes with the cluster intensities by beam attenuation and possibly cluster destruction.

During the measurements the neutral beam was well collimated so that no wall collisions could occur in the ionizer. However, the entrance grid of the ionizer had an 80 % transparency so that some clusters could be broken up there leading to an enhancement of the signals for low masses. That this effect is real was shown

in an experiment where we deliberately directed the molecular beam against the exit plate of the ionizer. At source pressures of about 600 torr a relative enhancement of the H_2^+ signal was observed by a factor two.

The H_3^+ signal does not originate purely from neutral clusters bombarded by electrons. At source conditions where no condensation can be expected ($T = 300^\circ\text{K}$, $p = 100$ torr), the H_3^+ signal still amounts to 0.5 % of the H_2^+ signal. In the ionizer, the reaction $\text{H}_2^+ + \text{H}_2 \rightarrow \text{H}_3^+ + \text{H}$ takes place between H_2^+ and incoming H_2 molecules producing a chopped and phase locked signal of mass 3.

This signal can also be caused partially by a modulation of the ionization efficiency. The ionization efficiency is space charge dependent and is sensitive to the modulated incoming molecular beam. In accordance with this picture we observed chopped and phase locked signals at all strong residual gas peaks.

The mass 9 signal indicates that the neutral parent cluster is formed at higher source pressures than the parent clusters for ions of smaller masses; the mass 9 signal, however, rises above all the other cluster intensities. We therefore believe that the mass 9 ion is especially stable. This conclusion gets support from the theoretical work of Huang et al.³ from which one derives as the most probable structure an equilateral triangle (H_3^+) with three H_2 molecules positioned outside the triangle on the lines from the centre through the midpoints of the three sides. This leads to a very symmetric and, as we infer, stable structure for the mass 9 ion. In accordance with this idea the behaviour of the mass 9 signal is barely reflected by the signals from the even masses, in Fig. 2. High stability was also found from ions of mass 15 by the group of Karlsruhe¹.

Owing to the uncertainties regarding the origin of the mass 3 signal eventual scattering measurements are most meaningful for clusters measured on the masses 5, 7, 9 etc. At 150 torr the ratio of intensities for mass 5 and mass 7 is about eight. All heavier ion masses have much smaller signals. Neutral clusters with mass 8 or heavier are practically absent in the molecular beam, under these conditions, as otherwise they would show up on mass 7, 9 and higher. In consequence one can safely assume that under these particular conditions the mass 5 cluster ion originates almost entirely from a parent cluster of mass 6. Similar conditions can be found for clusters of other molecular weights.

From total collision cross sections of $(\text{H}_2)_n$ with noble gases it may be possible to determine the relative contribution of different parent clusters to the ion signal at a certain mass, for various inlet pressures. Measurements with this aim are at present being performed in our laboratory.

VELOCITY ANALYSIS

Our velocity selector has a resolution $\Delta v/v = 12/35$ f.w.h.m. It can be used

Fig. 3. Maximum transmitted velocity against inlet pressure. \times are results for mass 2; \square for mass 3; \triangle for mass 5; \bullet for mass 7; \circ for mass 9; and \blacktriangle for mass 11. The velocity spread $\Delta v/v$ for mass 5 and heavier was purely instrumental (about 37 %); a deconvoluted $\Delta v/v$ (f.w.h.m.) for mass 2 is indicated in the upper part of the figure, with the scale on the right-hand side.

to measure the most probable velocity of the beam molecules and to some extent the velocity distribution (see Fig. 3). We roughly calibrated the selector by reversing the direction of rotation. Comparing the ratio of the rotation frequencies for both directions at maximum signal (the maximum transmitted velocity) gives an estimated absolute accuracy of the velocity determination of 5 %. The relative accuracy of our velocity measurements is about 1 %.

In Fig. 3 the results of the velocity analysis are shown. The extrapolated velocity value at zero source pressure is about 715 m sec^{-1} . This value must be compared with 465 m sec^{-1} , the most probable velocity of hydrogen molecules at 26°K , for effusive flow. Consequently, at the lowest source pressure used in our experiment we are already in the regime of a supersonic expansion.

The mass 2 signal shows a small increase with increasing source pressure. Theoretically one would expect a slight decrease as indicated by the broken line in Fig. 3. This decrease stems from the lowering of the enthalpy with higher pressures and was calculated from the discussion of the high pressure results found in ref. 4. In Fig. 3, mainly the different derivatives are of interest, in view of the 5 % absolute accuracy of our measurements. The behaviour of the mass 2 signal can be understood as follows. Clusters are formed in triple collisions where two partners stick together and the lighter third partner carries away the surplus of energy. This leads to a broadening of the H_2 velocities as indicated in Fig. 3. Experimentally, we determine as velocity distribution the product of the velocity selector transmission and the actual distribution in the molecular beam times $1/v$ due to the velocity dependence of the detector efficiency. In this product, the

maximum transmitted velocity for a broad distribution is shifted by about 10 % to a higher value compared with a very sharp distribution.

Another influence comes from the fact that at high source pressures the background pressure rises to such values that the beam signal from the H_2 molecules in the vacuum chamber surrounding the source is no longer negligible. As these molecules have a higher temperature they cause a shift of the most probable beam velocity to higher values. This shift becomes more pronounced at high inlet pressures.

The velocities of the clusters measured at mass 5, 7, 9 and higher as function of the source pressure all fall on one curve. This curve has a steeper slope than follows from enthalpy considerations. We tentatively interpret this difference as a consequence of the fact that with increasing pressure the ion signal on each mass comes from parent clusters of increasing weight. These clusters are formed before the expansion is terminated, because many (triple) collisions are needed to form a large cluster. After formation of a heavy cluster it seems obvious that further acceleration by the light H_2 molecules falls behind in comparison to the acceleration of the H_2 molecules themselves. Therefore, the most probable cluster velocity is shifted towards smaller values for the heavy clusters.

Mass 3 ions show a special effect. For low inlet pressures they originate partially from H_2^+ ions colliding in the ionizer with H_2 molecules from the beam. Therefore, the mass 3 signal behaves similarly to the H_2^+ signal. At higher pressures, however, the fraction originating from neutral clusters is increasing. In accordance, the mass 3 signal tends to join the curve of the heavier cluster ions.

(Received 22 April 1975)

ABSTRACT

Ar-cluster beams were produced by supersonic expansion under various source conditions. The experimental intensities have been scaled such that universal curves are obtained, up to moderate source pressures. The ratio of dimer/monomer cross-sections has been determined.

INTRODUCTION

Results of a molecular beam experiment with argon clusters are presented; special attention is given to dimers. Intensities of supersonic Ar beams with partial condensation have already been measured and interpreted by other workers [1–3] using mass spectrometry to analyse the beam. In the present work the emphasis is put on the determination of the total collision cross-section as a function of the stagnation pressure, P_0 , and stagnation temperature, T_0 . Pressures P_0 range from 20 to 6000 torr, at the four temperatures 294, 223, 173 and 123 K. The nozzle is made by piercing a 30 μm diameter hole (d) into a 25- μm thick stainless steel foil.

The apparatus has already been described in detail [4]. The magnetic mass spectrometer has a mass range up to about 160 a.m.u. The electron energy in the ionizer is fixed at 100 eV. The ionizer is tuned to work without any detectable ion space-charge in the ionization volume, thus ion-molecule reactions of the incoming beam with ions can be practically ruled out. In front of the ionizer the beam is collimated by a rectangular slit with an aperture of $0.4 \times 12 \text{ mm}^2$.

* This work is part of the research program of the "Stichting voor Fundamenteel Onderzoek der Materie (F.O.M.)" and has been made possible by financial support from the "Nederlandse Organisatie voor Zuiver Wetenschappelijk Onderzoek (Z.W.O.)".

The distance between the source and the detector is 205 cm. Because the ionizer has a high detection efficiency, we were able to extend our measurements to lower values of $P_0 d$ as compared to previous works [1-3].

MEASURED INTENSITIES

Intensities were measured for the ion masses 40, 80, 120 and 160. In a log-log plot (Fig. 1) each ion signal shows a rise in the onset region proportional to $P_0^{\alpha_m}$; α_m is different for different ion masses, but independent of the temperature T_0 over the range investigated. Values for α_m are given in Table 1.

For different temperatures T_0 , the stagnation pressure P_0 can be scaled by $T_0^{\beta_m}$ so that for each ion mass the intensities are represented by a single curve (see Fig. 1). Values of β_m for different ion masses are shown in Table 1.

Fig. 1. Intensities vs. reduced stagnation pressure. I corresponds with the Ar^+ , II with the Ar_2^+ , III with the Ar_3^+ and IV with the Ar_4^+ signal. Measurements were done at source temperatures $T_0 = 294$ K (●), 223 K (▲), 173 K (△) and 123 K (○). No scaling is applied on the ordinate for different T_0 ; the pressures, however, are multiplied by $(294/T_0)^{\beta_m}$. The values for β_m are different for the four curves and are given in Table 1. Above the reduced pressure \bar{P}_L the Ar_2^+ signal becomes contaminated by fragments from larger clusters - see Fig. 2.

TABLE 1

VALUES FOR THE EXPONENT α_m AND β_m ^a

| m | α_m | β_m | $\alpha_m\beta_m$ | $\alpha_m\beta_m-0.5$ | $\alpha_m(G)$ |
|------------|----------------|-----------------|-------------------|-----------------------|---------------|
| 1 | 1.1 \pm 0.1 | 1.05 \pm 0.15 | 1.2 | 0.7 | 1.1 |
| 2 | 2.15 \pm 0.1 | 1.9 \pm 0.1 | 4.1 | 3.6 | 2.5 |
| 3 } 4 } | 5.5 \pm 0.5 | 2.2 \pm 0.1 | 12 | 12 | 3.6 |

^a In the onset region the signal of Ar_m^+ ions varies with $P_0^{\alpha_m} T_0^{-\alpha_m\beta_m}$ at a fixed temperature. For different temperatures the signal is proportional to $P_0^{\alpha_m} T_0^{-\alpha_m\beta_m}$. The exponent $(-\alpha_m\beta_m)$ of T_0 should be replaced by $(-\alpha_m\beta_m+0.5)$ if neutral beam intensities instead of neutral beam densities are considered. The values $\alpha_m(G)$ derived from ref. 1b, Fig. 7, are given for comparison.

The intensities in Fig. 1 are presented as a function of a reduced pressure $\tilde{P}_0 = P_0 \cdot (294/T_0)^{\beta_m}$. The measured intensities are seen to be proportional to $P_0^{\alpha_m}/T_0^{\alpha_m\beta_m}$ in the onset region. The exponent $\alpha_m \cdot \beta_m$ must be decreased approximately by 0.5 when the intensity is to be expressed as beam flux instead of beam density.

At higher stagnation pressures all intensities go through a maximum. For $m/e = 40$ (the argon monomer signal¹) this can be attributed to an increased loss of particles due to condensation. Not only are argon atoms swallowed up by the condensating clusters but also other atoms acquire extra momentum from the heat of condensation and will escape from the collimated beam. At corresponding stagnation conditions an increase in forward velocity [1b] and a sudden rise in effective source diameter [5] has been observed.

For the maximum of the dimer signal, scaling factors for cluster beams of argon are available [1b]. However, we prefer a scaling for the intensity in the onset region of the dimer ion signal because effects due to heavier clusters are small there, as will be discussed below.

The pressure dependence of the different ion signals at constant T_0 was derived from the work of Golomb et al. [1b] and is shown in the last column of Table 1. The apparent disagreement with our results is due to the fact that Golomb et al. worked with larger nozzle diameters. The results of Milne et al. [2] do not lend themselves to the determination of the pressure dependence, directly. However, if we compare our relative intensities at room temperature and high pressures with data of Fig. 5 from ref. 2a, good agreement is found within a factor 1.2 for the dimer-ion signal.

The pressure and temperature dependence found by Yealland et al. [3] for the argon dimer concentration is derived from relatively high stagnation pressures and does not agree with our findings in the onset region; for $P_0 < P_L$, see Fig. 1. The scaling laws of Hagena [6] predict a value of $\alpha_2\beta_2 - \alpha_1\beta_1 \simeq 2.3$; we find the value 2.9 ± 0.3 for this quantity.

The total attenuation of the signal on each ion mass was measured. For a $1/e$ attenuation of the monomer beam by argon at 80 K, an Ar pressure of about 10^{-4} torr is needed over an experimental scattering length of 5 cm.

The angular resolution is estimated by the method of v. Busch [7] to amount to a 2 % (4 %) correction for the monomer (dimer) cross-section at $T_0 = 300$ K, assuming the total cross section to be 400 \AA^2 (560 \AA^2).

The attenuated intensity for mass m , I_m , depends on the pressure of the scattering chamber as $I_m = I_{m,0} \exp(-\sigma_m \cdot p_{s.c.} \cdot \text{const})$. Therefore, we define a log attenuation La (being proportional to the effective total collision cross-section σ_m) as $La = -(10^{-5}/p_{s.c.}) \log I_m/I_{m,0}$, where $p_{s.c.}$ is measured in torr.

In Fig. 2 the results for $T_0 = 173$ K are presented; the results for other T_0 are very similar. The La for mass 40 is independent of P_0 below 1500 torr. For $T_0 = 294$, 223 and 123 K the stagnation pressures below which the La for the monomer is constant are 6000, 3000 and 700 torr, respectively. The values of La for different T_0 are corrected for the velocity spread in the scattering chamber (using formulas of Bernstein [8]) and for the finite angular resolution. [7]. The total cross-section thus found varies approximately with $v_{rel}^{-2/5}$, the velocity dependence for an r^{-6} interaction potential. For the relative velocity, the value

Fig. 2. Log attenuations vs. stagnation pressure P_0 , at the stagnation temperature $T_0 = 173$ K. The log attenuation La_n is proportional to the effective collision cross-section of neutral Ar_n with Ar in the scattering chamber. The quantity La^+ is related to these log attenuations; it is the measured log attenuation for the Ar^+ (I), Ar_2^+ (II), Ar_3^+ (III), and Ar_4^+ signal (IV). For a unique correspondence between an ion signal and a specific neutral cluster Ar_n , the La^+ equals La_n and is, thus, independent of P_0 . Above the stagnation pressure P_L , this unique correspondence is lost for the Ar_2^+ signal.

belonging to full isentropic expansion [9] is taken. Glory undulations are unobserved; they are calculated to be small and completely averaged by the large spread of the relative velocity.

For $T_0 = 173$ K and pressure P_0 higher than 1500 torr the La yields lower values for the monomers. This can be caused by the increase in velocity of the beam [1b] and the deterioration of the angular resolution resulting from the larger effective source diameter [5]. Both effects have been discussed above.

For the dimer signal at mass 80 with $T_0 = 173$ K the La is constant within the experimental accuracy for stagnation pressure P_0 below $P_L = 600$ torr, see Fig. 2. Corresponding pressures P_L are 1800, 1000 and 300 torr for 294, 223 and 123 K, respectively. At higher pressures the La rises and goes through a maximum. When these pressures P_L are multiplied by $(294/T_0)^{\beta_2}$ (the value for β_2 obtained from our intensity measurements, as shown in Table 1, is used) an unique value \tilde{P}_L is found, indicated by the arrow in Fig. 1. In our opinion, \tilde{P}_L marks the relatively sudden appearance of larger clusters. For all T_0 , larger clusters show up at the same dimer intensity.

Since the La is constant for $P_0 < P_L$ and no ion signals of larger clusters can be detected there (see Fig. 1) and since we find the correct pressure dependence ($\alpha_1 = 1.1 \pm 0.1$ and $\alpha_2 = 2.15 \pm 0.1$) we attribute the ion signal at mass 80 to the ionization product of neutral Ar_2 for $P_0 < P_L$. The constant value of La corresponds to the total effective dimer collision cross-section, averaged over all vibrational and rotational states. After correction for the finite angular resolution of our apparatus the total collision cross-section for the $\text{Ar}_2\text{-Ar}$ system is found to be a factor 1.40 ± 0.05 larger than for the Ar-Ar system, independent of T_0 . This means that the C_6 -factor of the intermolecular potential is roughly twice as large for the dimer as for the monomer.

The rise of La for $P_0 > P_L$ is attributed to admixture of heavier polymers which in general will have larger cross-sections and will contribute to the signal at $m/e = 80$ by dissociative ionization. A signal of the larger cluster ions is detected at a pressure slightly above P_L (see Fig. 1).

The levelling off of the La at $m/e = 80$ is attributed to scattering and break-up of beam clusters by the background in the source chamber.

For larger clusters, La -results are also given in Fig. 2; for $m/e = 120$ the La -values are independent of P_0 , for $m/e = 160$ they are slightly smaller and vary somewhat with P_0 . Under the (very questionable) assumption that the $m/e = 120$ signal does correspond to the trimer and the $m/e = 160$ signal to the quadramer, we have estimated the relative total collision cross-section from the measured La . The same value is found for trimers and quadramers, after applying the angular resolution correction, (about 6 % and 8 %) to the La [7].

It seems more realistic to abolish the idea of a simple correspondence between neutral trimers and quadramers and the Ar_3^+ and Ar_4^+ signals and to face the possibility that the signals at $m/e = 120$ and 160 are for a large part due

to fragments of larger clusters. This possibility accords with the model that in supersonic nozzle beams at low P_0 only monomers and dimers are present, and that larger polymers (which suffer large dissociation at ionization) show up suddenly when a critical pressure is exceeded. The experimental pressure dependence of the trimer- and quadrumer-ion signal is the same, $\alpha_3 = \alpha_4 = 5.5 \pm 0.5$. (If the polymers could be produced under equilibrium conditions in the source, $\alpha_3 = 3$ and $\alpha_4 = 4$ would be expected.) The large exponents are at least compatible with the supposition that the ion signals at $m/e = 120$ and 160 originate, for a large part, from dissociative ionization. Let us assume, then, that the signals at $m/e = 120$ and 160 are due to a representative neutral parent of mass m , with an intensity I_m and an effective La_m equal to the measured average La at $m/e = 120$ and 160 (see Fig. 2, where the log attenuations are shown for a scattering pressure of 10^{-5} torr; in the actual experiment about $3.4 \cdot 10^{-5}$ torr was used).

With this assumption we are able to estimate the ratio of detection probabilities $q_{m,3}/q_{m,2}$. Here, $q_{m,i}$ includes the probability of dissociative ionization of the neutral Ar_m cluster resulting in the ion cluster Ar_i^+ as well as the transmission of the mass spectrometer and the multiplier efficiency for this ion. One has

$$I_{2,0}^+ = q_{2,2} I_{2,0} + q_{m,2} I_{m,0} \quad (1)$$

$$I_{3,0}^+ = q_{m,3} I_{m,0} \quad (2)$$

and

$$I_{2,0}^+ \exp(-3.4La_2^+) = q_{2,2} I_{2,0} \exp(-3.4La_2) + q_{m,2} I_{m,0} \exp(-3.4La_m) \quad (3)$$

The log attenuation La_i^+ is proportional to the effective cross-section, measured for the ion signal on mass i as shown in Fig. 2.

From eqns. (1) and (2), it follows that

$$\frac{q_{m,3}}{q_{m,2}} \cdot \left[\frac{q_{m,2} I_{m,0}}{q_{2,2} I_{2,0}} \right] = \frac{I_{3,0}^+}{I_{2,0}^+} \left(1 + \left[\frac{q_{m,2} I_{m,0}}{q_{2,2} I_{2,0}} \right] \right) \quad (4)$$

The ratio $I_{3,0}^+/I_{2,0}^+$ is experimentally determined, see Fig. 1. The quantity

$$\left[\frac{q_{m,2} I_{m,0}}{q_{2,2} I_{2,0}} \right]$$

is related to the observed attenuations by

$$\left[\frac{q_{m,2} I_{m,0}}{q_{2,2} I_{2,0}} \right] = \frac{\exp(-3.4La_2) - \exp(-3.4La_2^+)}{\exp(-3.4La_2^+) - \exp(-3.4La_m)} \quad (5)$$

If we now use for $T_0 = 173$ K the values $La_2 = 0.150 \pm 0.003$, $La_m = 0.195 \pm 0.005$ and $La_2^+ = 0.157 \pm 0.002$ at $P_0 = 800$ torr or $La_2^+ = 0.164 \pm 0.002$ at $P_0 = 1000$ torr (see Fig. 2), we obtain values for $q_{m,2}/q_{m,3}$ between 10 and 20. Thus, we find a high relative probability to detect a neutral cluster of mass m as an Ar_2^+ ion.

For the other values of T_0 the ratio $q_{m,2}/q_{m,3}$ is found between the same limits.

From eqn (5) it is found, from the given values of La_2 , La_m and La_2^+ that $q_{m,2}I_{m,0}/q_{2,2}I_{2,0}$ equals 0.2 at 800 torr and 0.5 at 1000 torr. This result indicates a strong admixture from large neutral clusters to the dimer signal, already at pressures slightly above P_L . Most of the measurements of Milne et al. [2] were done at stagnation pressures higher than P_L , therefore, the conclusions on rate constants of dimer formation should be taken with reserve. To perform measurements below P_L one really needs a very sensitive detector, otherwise the dimer ion signal is buried in noise (see the limited pressure range of constant attenuation in Fig. 2).

In a forthcoming paper we shall show that our experimental dimer results are in agreement with thermodynamic equilibrium predictions, based upon the assumption that the dimers are "prefabricated" in the source.

Fig. IV.1. Schematic view of the apparatus.

The cluster beam is formed by the expansion of gas from the nozzle source **S** and by the conical skimmer **Sk**; it passes through the scatterbox **Sb** and the Rabi type magnet **R**. The beam is collimated by a slit of the scatterbox and the detectorslit **D**. After **D** the cluster beam enters the ionizer **I**; the ions are mass selected in magnet **MSM** and amplified by electron multiplier **M**. Reversing the magnetic field in **MSM** the ions can be used for further experiments ("ion scattering"). All distances given are in mm.

IV INTENSITIES AND CROSS SECTIONS OF Ne, H₂, N₂, NO AND O₂ CLUSTERS IN A MOLECULAR BEAM

IV 1 INTRODUCTION

Pursuing our earlier effort (ref 1), we have investigated molecular beams of Ne, H₂, N₂, NO, and O₂ clusters. The temperature and pressure dependence of the ion signals have been measured for masses up to three times the monomer mass.

The neutral beam is attenuated by argon- or helium-gas in a scatterbox. While the total collision cross section itself is of interest, it serves at the same time to check what neutral parent belongs to a certain ion mass (ref 1). Only for monomers and dimers we were able to determine a "clean" cross section.

For Ar we have been able to plot the intensities vs. reduced source pressures P_{red} , such that for all source temperatures T_0 , a single curve is obtained for each ion mass. The aim of this investigation is to test whether a similar reduction is also possible for another noble gas, Ne, for a nearly noble gas, H₂, and also for diatomic molecules, N₂ and NO.

For H₂ and the paramagnetic gases NO and O₂, the magnetic properties of the dimer have been compared with those of the monomers, using a Rabi type deflection magnet of 40 cm length and a maximum field gradient of 20 kGauss cm⁻¹.

In addition to the insertion of this deflection magnet, the original set-up described in ref 1 has been changed by replacing the small mass spectrometer magnet by a more powerful one (a switching magnet, model 1038, Spectromagnetic Industries, 14 cm pole diameter). At 900 eV ion energy the mass range extends up to 2500 amu.

All measurements have been done using a 26 μ nozzle diameter. The distance between source and scatterbox amounts to 65 cm, that between the source and detector slit to 195 cm. Good collimation of the beam is ensured by the rectangular opening of the scatterbox, 0.4 x 12 mm², and the slit in front of the detector, 0.8 x 8 mm². Extra collimation at the source was tried but never felt necessary. A view of the apparatus is given in fig. IV 1.

IV 2 THE INTENSITIES

In fig. IV 2a the intensities are drawn as a function of the reduced pressure for the isotopes of the Ne-monomer and for their dimers. The Ne-gas used has the natural composition, 90.92% ²⁰Ne, 8.82% ²²Ne, 0.257% ²¹Ne. The figure shows the ²⁰Ne monomer intensity divided by a factor 10, in consequence it coincides with the ²²Ne monomer, the omitted signal of the other isotope scales according to its natural abundance.

Fig. IV.2. Intensity vs. reduced pressure for Ne (a) and H_2 (b). In the left part of the figure the symbol I corresponds to the $^{20}Ne^+$ intensity divided by a factor 10; the $^{22}Ne^+$ intensity at $T_0 = 65K$ is indicated by x. The symbol IIa corresponds to $^{20}Ne_2^+$, IIb to $^{20}Ne^{22}Ne^+$, and III to $^{20}Ne_3^+$. In the right part of the figure the symbol I belongs to H_2^+ , II to H_3^+ and III to H_5^+ . The monomer intensity (I) is displayed divided by a factor 10. The intensities are measured at temperatures $T_0 = 100K$ (\blacktriangle), $T_0 = 65 K$ (\triangle , x), and $T_0 = 33 K$ (O). For H_2 we have added the intensities for $T_0 = 273K$ (\bullet , monomer only) and $T_0 = 28 K$ (\square).

The abscissa represents the true pressure P_0 in torr for $T_0 = 65 K$.

At other temperatures reduction factors P_0/P_{red} are applied for each ion mass, see table IV.I. At the reduced pressure \tilde{P}_L the dimer signal becomes contaminated by fragments of larger clusters.

For a source temperature $T_0=65K$ the reduced pressure P_{red} equals the true source pressure P_0 ; for other temperatures the reduction factors are given in table IV.1.

No scaling other than for the monomer ion isotopes is applied in vertical direction. At higher pressures the intensity curves start to diverge, the high temperature ones always above the low temperature ones. This behaviour stems from the fact that at lower source temperatures the production of heavier clusters takes place at lower reduced pressures, causing a decrease of intensity. Also, heavier clusters start to appear; Ne_5^+ ions are observed but not shown in fig. IV.2.

The dimer ion isotopes have a constant ratio of intensities, $I_{40}/I_{42} \simeq 4$, as expected from statistical considerations.

In fig. IV.2b the results for H_2 are given. As discussed in ref. 2 we have observed ions H_2^+ , H_3^+ and H_5^+ ; also higher masses were detected (ref. 2), but

are not considered in the present work. For the reduction factors P_0/P_{red} see table IV.1.

For the monomer ion signals the diverging tendency at high pressures is similar to that observed for Ne and Ar (ref. 1). However, for the H_3^+ -ion the sequence is reversed. In our interpretation the reversal is caused by significant fragmentation of heavy clusters into H_3^+ -ions in the ionizer.

In fig. IV.3a and 3b the intensities are given for N_2 and NO, respectively, for temperatures T_0 between 130 K and 300 K. In table IV.1 the reduction factors P_0/P_{red} are given. Signals of heavier clusters have been observed, for instance up to N_{14}^+ , but are not displayed in fig. IV.3. Contrary to the case of H_2 , here the ions of even mass have intensities stronger than those of odd mass. For instance, forty times the N_3^+ -signal is observed on N_4^+ , whereas fifty times the H_6^+ -signals equals roughly the H_5^+ -signal (ref. 2).

The pressure range where we can draw a straight line through the results in fig. IV.2 and 3 is called the onset region. The cross section results of the following section show that in this region the monomer (dimer) ion signals originate from neutral monomers (dimers).

caption to fig IV.3

Fig. IV.3. Intensities vs. reduced pressure for N_2 (a) and NO (b).

The intensities are measured at source temperatures $T_0 = 296$ K (\bullet), $T_0 = 223$ K (\blacktriangle), $T_0 = 173$ K (Δ), and $T_0 = 133$ K (O). The abscissa represents the true pressure P_0 in torr for $T_0 = 233$ K. At other temperatures reduction factors P_0/P_{red} have been applied, see table IV.1. The monomer ion signal (I) is displayed, divided by a factor 10; The dimer ion signals N_4^+ and $(\text{NO})_2^+$ are indicated by II. For N_2 the reduced value \tilde{P}_L is indicated; no \tilde{P}_L can be defined for NO.

Table IV.2. Exponents α_m and β_m for the intensities in the onset region.

In the onset region the measured intensities $I^+_{m,0}$ are approximately proportional to $P_0^{\alpha_m} / T_0^{\alpha_m \beta_m}$, $m = 1$ for the Ne⁺, H₂⁺, N₂⁺ and NO⁺ signals, $m = 2$ for the Ne₂⁺, H₃⁺, N₄⁺ and (NO)₂⁺ signals. Values for α_m and β_m are shown in table IV.2.

The pressure dependence of $I^+_{m,0}$ is in accordance with expectation, $\alpha_1 \simeq 1$. For $I^+_{2,0}$ one expects a proportionality with the squared density of the monomer in the source.

Experimentally we find $\alpha_2 = 2.0 \pm 0.1$ for Ne, Ar (ref.1) and H₂; for N₂, NO and O₂, however, we find $\alpha_2 = 2.5 \pm .2$, $2.8 \pm .1$ and $2.7 \pm .2$, respectively.

Even a simple equilibrium theory for dimer concentration predicts a much more complicated temperature dependence than the proportionality with $T_0^{-\alpha_2 \beta_2}$. However, for the limited temperature range investigated this approximation gives the right reduction factor P_0/P_{red} within 7% for Ne and H₂, within 6% for N₂ and within 9% for NO.

With respect to ref. 1 the scattering technique has been improved attaching an ionization gauge directly to the 80 K scatterbox (see also ref.3). The filament of the gauge is mounted under tension to prevent geometrical changes during operation. Thereby, the reproducibility is kept within 1% per day. During long measuring periods the gauge is not switched off for weeks. To attenuate the neutral beam a pressure of about 10^{-4} torr is maintained in the scatterbox; for the unattenuated beam the box is pumped down to about 2×10^{-7} torr.

In fig. IV.4a and 4b the total collision cross section results for Ne and H_2 are displayed with a light and a heavy scattering partner, respectively. As in ref.1 we are able to define a pressure limit \tilde{P}_L , below which the dimer ion signal corresponds to a neutral dimer parent. The range for \tilde{P}_L indicated in fig. IV.2, 3, 4 and 5 is obtained by dividing the P_L values by the reduction factors for the dimer intensities (see table IV.1) A general criterion will be discussed in the next section.

The velocity of the beam molecules, v_1 , has been calculated from the source temperature T_0 assuming full isentropic expansion, $v_1 = (2C_p T_0)^{1/2}$; C_p is the specific heat at constant pressure per unit mass. The average relative

Fig. IV.4. Apparent cross section vs. reduced pressure for Ne (a) and H_2 (b) of monomers (I) and dimers (II).

The different symbols correspond to different temperatures, $T_0 = 100$ K (\blacktriangle), $T_0 = 65$ K (\triangle); for Ne the results at $T_0 = 33$ K (\circ), for H_2 those at $T_0 = 166$ K (\bullet) and $T_0 = 30$ K (\circ) are added. As target molecule He is used for Ne, and Ar for H_2 . The ordinates are logarithmic; at all values of T_0 the average value of σ_1 is taken equal to unity for both Ne and H_2 . The abscissa represents the true pressure P_0 for $T_0 = 65$ K; at other temperatures reduction factors have been applied, see table IV.1. For $T_0 = 166$ K interpolated reduction factors are used. For $P_{red} \leq \tilde{P}_L$ the dimer cross section is determined. The results for both Ne isotopes are shown together. The dimer measurements for Ne do not extend to very low pressures because of detector noise due to residual background ions. For Ne no variation in σ_2/σ_1 is found, for H_2 a slight variation with T_0 is apparent. The shaded regions for \tilde{P}_L are obtained by a reduction of P_L with the same factors as for the dimer intensities, see table IV.1.

velocity v for different scattering partners has been calculated from v_1 and the thermal velocity of the scatter gas, α_s ; $v = (v_1^2 + \alpha_s^2)^{1/2}$. Fig. IV.4 shows that the velocity dependence of σ_2/σ_1 , the ratio of dimer and monomer cross section, is small or negligible. For this reason we refrained from a more accurate velocity determination.

In fig. IV.5a and b similar results are given for N_2 and NO. No velocity dependence of σ_2/σ_1 is detected. With a heavy scattering partner, the value of σ_2/σ_1 equals $1.34 \pm .02$ for NO, $1.40 \pm .03$ for N_2 , and $1.40 \pm .02$ for O_2 . The ratio found for Ar (cf. ref. 1) is $\sigma_2/\sigma_1 = 1.39 \pm .02$, for Ne $\sigma_2/\sigma_1 = 1.35 \pm .05$. For H_2 the values range from $\sigma_2/\sigma_1 = 1.36 \pm .02$, at $v_1 \approx 1200 \text{ msec}^{-1}$, to $\sigma_2/\sigma_1 = 1.55 \pm .04$, at $v_1 \approx 1900 \text{ msec}^{-1}$.

For the light scattering partner (He) larger σ_2/σ_1 ratios are found, generally; $\sigma_2/\sigma_1 = 1.64 \pm .02$ for N_2 , $\sigma_2/\sigma_1 = 1.57 \pm .05$ for O_2 ; $\sigma_2/\sigma_1 = 1.77 \pm .02$ for Ne and $\sigma_2/\sigma_1 = 1.96 \pm .06$ for H_2 . For the molecular system NO the ratio σ_2/σ_1 is found slightly smaller, $\sigma_2/\sigma_1 = 1.51 \pm .02$.

The angular resolution correction is applied to σ_2/σ_1 following ref. 4. For the heavy scattering partner, where the interaction is dominated by a r^{-6} -attraction, this correction equals roughly the experimental uncertainty. The relative correction due to the spread in relative velocity is the same for σ_2 and σ_1 (ref. 5.). The light collision partner poses the problem that the angular resolution correction according to ref. 4 becomes rather inaccurate for two reasons. Firstly, the velocity dependence is not in agreement with a pure r^{-6} -potential. Secondly, the velocity of the target molecules is comparable to v_1 ; in this case the formulas of ref. 4 are not properly valid. Lack of a better procedure has forced us neverthe-

Fig. IV.5. Apparent cross section vs. reduced velocity for N_2 (a) and NO (b) of monomers (I) and dimers (II).

The different symbols correspond to different temperatures, $T_0 = 296 \text{ K}$ (●), $T_0 = 223 \text{ K}$ (▲), $T_0 = 173 \text{ K}$ (Δ), and $T_0 = 133 \text{ K}$ (○). The abscissa represents the true pressure P_0 in torr for $T_0 = 223 \text{ K}$; for other temperatures a reduction is applied equal to that for the intensities (table IV.1). For both N_2 and NO, Ar is used as target gas. For all temperatures σ_1 is independent of the source pressure and is taken equal to unity. For N_2 a pressure \tilde{P}_L is defined; from reduced pressures $P_{\text{red}} \leq \tilde{P}_L$ the dimer cross section σ_2 is determined. For NO the cross section σ_2 is constant up to the highest pressures, where ion signals of larger clusters are already present. Both for N_2 and NO, the ratio σ_2/σ_1 is equal for all T_0 .

less, to use the correction method of ref. 4. The statistical error given for σ_2/σ_1 does not include the uncertainty of this correction

The discussion of the ratio σ_2/σ_1 for a heavy scattering partner can be based on the expression for the total collision cross section (ref. 6)

$$\sigma_{\text{tot}} = 8.083(C_6/\hbar v)^{2/5} \quad (\text{IV } 1)$$

From eq. IV.1 follows $C_{6,d}/C_{6,m} = (\sigma_2/\sigma_1)^{5/2}$. Consequently, $\sigma_2/\sigma_1 = 1.32$ yields $C_{6,d} = 2C_{6,m}$ (ref. 1). Observed ratios 1.34 - 1.45 correspond to $C_{6,d}/C_{6,m}$ between 2.0 and 2.5. This ratio appears reasonable to us; theoretical predictions for $C_{6,d}/C_{6,m}$ do not exist at this moment.

For H_2 -Ar scattering and wherever He is used as scattering partner, glories in the total collision cross section might have been expected. However, due to the velocity averaging for He (average velocity in the 80K scatterbox 600 msec^{-1}) the glories are smoothed out entirely. With the H_2 -beam this averaging effect is much smaller because here the heavy and slow partner is in the scatterbox. Here, σ_2/σ_1 is found to vary slightly over the large velocity range, v_1 between 800 and 1850 msec^{-1} .

If one neglects all possible inelastic events (rotational excitation and dissociation of the loosely bound $(\text{H}_2)_2$ -complex), one can calculate σ_2/σ_1 under simplifying assumptions concerning the interaction potential. In fig. IV.6 results of such a calculation are shown.

The monomer cross section is calculated (ref.7) for the Lennard Jones potential with ϵ and R_m taken from ref. 3. Our measured monomer cross section σ_1 (fitted to the calculated value at 1180 m sec^{-1}) agrees with the calculations to within the experimental error. The spread in relative velocity due to the thermal velocity of the target gas is indicated by the horizontal bars on σ_1 .

In fig. IV.6. the experimental points of σ_2 are derived from the calculated σ_1 and the measured ratios σ_2/σ_1 .

We calculated (ref. 7) a dimer cross section for various sets of Lennard Jones parameters. A reasonable fit is shown in fig. IV.6, for $C_{6,d} = 2.5C_{6,m}$ (IIa) and $2.7C_{6,m}$ (IIb); the product ϵR_m is kept constant and taken equal to the monomer value because this guarantees the absence of glory undulation in σ_2/σ_1 .

The $C_{6,d}/C_{6,m}$ value obtained are similar to the results for the heavier systems.

IV.4 THE MAXIMUM PRESSURE P_1 FOR PURE DIMER BEAMS

One main result of this work is the firm establishment of experimental conditions under which the dimer ion signal corresponds to pure dimers, with negligible contamination from fragments of heavier clusters. For each source

Fig. IV.6. Calculated and measured cross section σ_2 and σ_1 vs. velocity for H_2 -Ar.

The curve indicated by (I) represents the calculated monomer cross section. The measured cross section σ_1 is put equal to the calculated cross section at $v = 1180$ m/sec. The monomer cross section at $v = 1460, 810$ and 760 m/sec follow from this choice and are then equal to the calculated ones within their errors. The dimer cross sections are obtained from the measured ratios σ_2/σ_1 . The curves IIa and IIb are calculated for $C_{6,d} = 2.7 C_{6,m}$ and $2.5 C_{6,m}$ respectively, with $C_{6,m} = 2.80 \times 10^{-11}$ erg. \AA^6 ; $\epsilon R_m = 3.37 \times 10^{-14}$ erg. \AA is taken equal for monomers and dimers.

temperature T_0 we find a limit pressure P_L below which the simple correspondence prevails. The values of P_L are collected in table IV.3. The limit pressure is of technical interest to those who want to design experiments. Therefore, we tried to condense our experience into a simple prescription using the intermolecular potential depth ϵ and the minimum position R_m as scaling parameters.

All our measurements on the noble gases Ar and Ne, and H_2 and N_2 , performed with a $d_0 = 26 \mu$ nozzle diameter, lead to P_L -values given by the following equation (within a factor 1.3)

$$P_L = 0.6 \times \epsilon R_m^{-3} \cdot \{kT/\epsilon\}^{(2-3\kappa)/(2-2\kappa)} \cdot (R_m/d)^{.55} \quad (IV.2)$$

Eq. IV.2 is not in contradiction with the general formulas given in ref. 8; actually, the temperature dependence corresponds with the lower limit of Hagen and Obert. The temperature dependence for Ar and N_2 agrees, too, with the temperature dependence observed by Golomb et al. (ref. 9) for the pressure corresponding to the maximum of the dimer ion signal. At this pressure large clusters are abundantly present in the beam. Its value is about three times higher than the value of P_L , as can be seen from fig. III.1, or calculated from the experimental result and the scaling laws of ref. 9.

Eq. IV.2 is tested for $d = d_0 = 26 \mu$, only. The last factor is added in view of the evidence (ref. 9) that beam condensation is determined by the product $P_0 \cdot d^{.55}$, at fixed source temperature. The scaling of the nozzle diameter d with R_m is in accordance with the principle of corresponding jets (ref. 8).

Table IV.3. Values of P_I in torr at various T_0 for Ne, H₂, Ar, and N₂.

The dimer signal of NO forms an exception; here no contribution from fragmentation of larger clusters to the dimer ion signal is indicated by our measurements. At the maximum source pressure used many heavier clusters are present in the beam and the dimer ion signal levels off already.

IV.5 MAGNETIC DEFLECTION

We have looked for information concerning the magnetic properties of dimers of H₂, NO and O₂ in the beam by measuring their deflection in an inhomogeneous magnetic field.

For a well collimated H₂-beam at 26 K source temperature ($v_1 = 750$ m/sec) the ortho-monomers in the $m_l = \pm 1$ state can be bent off the beam axis. We have varied the position of a slit (.1 mm width) in front of the Rabi magnet. For a broad H₂-beam the three m_l -states are clearly resolved; at three different slit positions distinct maxima of the signal are observed (see also ref. 10).

Without a magnetic field the dimer beam is sharply peaked, corresponding to good collimation of the beam. With magnetic field on, a broad distribution is measured by varying the slit position. The f.w.h.m. of the distribution is equal to the separation of the two $m_l = \pm 1$ states for the monomer. This indicates that the H₂-dimers in the beam have magnetic moments comparable to those of the

H₂-monomers. Consequently, the H₂-dimers can be investigated by magnetic resonance spectroscopy, a method described in detail by Ramsey (ref. 11). The total signal of pure dimers amounts to 1% of the monomer signal at maximum.

In the liquid phase, dimers of NO are known to be diamagnetic; also solid NO is found to consist of diamagnetic NO-dimers. On the other hand, the paramagnetism of O₂ is preserved in the liquid phase. However, from analysis of magnetic susceptibility it has been suggested that in O₂ at low temperatures some molecules form nonmagnetic dimers (ref. 13). Knobler (ref. 14) has sought evidence for these nonmagnetic dimers in the liquid.

We have investigated whether gaseous dimers of NO and O₂ possess magnetic moments. The decrease of the dimer intensity due to the inhomogeneous magnetic field is compared with that of the monomer intensity.

For NO-monomers a slow monotonous decrease is observed to about 40% of the full beam at the highest field gradient obtained in our experimental set up, about 20 kGauss.cm⁻¹. At low magnetic field no sudden decrease has been found due to the deflection of the $\Pi_{1/2}$ -state. This agrees with the experimental result (ref. 15) that in a nozzle expansion the electronic temperature (calculated from the relative population of the $\Pi_{1/2}$ and the $\Pi_{3/2}$ states) decreases similarly to the translational temperature. In the highly expanded jet of our experiment the $\Pi_{3/2}$ -state may be completely depopulated.

For NO dimers no decrease because of the magnetic deflection is detected. The absence of a magnetic moment can be explained in two ways. If paramagnetic $\Pi_{3/2}$ molecules are present in the beam, it is not likely that they will form stable dimers with other molecules. The energy of the electronic excitation exceeds the binding energy of the dimer. Because many degrees of freedom are coupled in a dimer, this energy can be transferred to rotation and vibration, causing dissociation. We are left with the diamagnetic dimers of two $\Pi_{1/2}$ molecules only. On the other hand, assuming that a dimer containing one or two $\Pi_{3/2}$ molecules has a lifetime long enough to reach the detector, its magnetic moment will be averaged to zero by the end over end rotation, in first order. For the end over end rotation large quantum numbers are allowed, see sect. VI.3.

The O₂-monomer signal drops to about 30% of its maximum value at low fields already, due to the deflection of the $^1\Sigma(m_s = \pm 1)$ states. At higher fields the signal approaches zero because the $^1\Sigma(m_s = 0)$ state is also deflected now, due to its small magnetic moment originating from the rotation of the molecule coupled to the electronic spin. We observe that O₂ dimers can be deflected, too; the maximum obtainable decrease of signal is about 70%. Therefore, O₂ dimers are paramagnetic. We consider the dispute about the appearance of diamagnetic O₂ dimers as settled (ref. 14). There are none.

Paramagnetic O₂ dimers will be interesting objects for a magnetic beam resonance study, although intensity problems may be severe. Admixture of He may improve the situation (see sect. VII.4).

V EXPERIMENTAL INVESTIGATION OF SMALL He CLUSTERS

A. P. J. van Deursen and J. Reuss

Katholieke Universiteit, Fysisch Laboratorium, Toernooiveld, The Netherlands
(Received 16 December 1974; revised paper received 2 September 1975)

The question of the existence of a bound van der Waals complex for He_2 has received attention in the literature recently. Accurate scattering studies by Farrar and Lee¹ and by Bennewitz *et al.*² suggest the absence of a bound state for the He_2 system. The potentials obtained are in fair agreement with theoretical results by Bertoncini and Wahl³ and by Schaefer *et al.*⁴ However, as is discussed by Bennewitz,² a 1.4% increase in the potential depth suffices to accomodate one bound state with zero angular momentum.

In the course of measurements of the production of molecular clusters⁵ we have searched for helium clusters. In our molecular beam machine we are able to cool the source to 6 K. The source pressure P_0 can be varied up to 6 atm for a nozzle diameter of 6 μ . The beam is detected by a magnetic spectrometer.⁵ The ionizer is adjusted to work without any detectable space charge.

The measured intensities of the ions He_n^+ , $n = 1-4$ are given in Fig. 1(a) as a function of P_0 , at $T_0 = 7$ K. He_2^+ ions are observed for values of P_0 larger than 200 torr. The intensity of He^+ increases linearly with P_0 for $P_0 < 400$ torr, and the intensity of He_2^+ varies with P_0^3 up to $P_0 = 800$ torr. Above 1100 torr the He_3^+ and He_4^+ ions appear; their intensity is roughly proportional to P_0^{10} . The heaviest ion detected at 1500 torr was He_{13}^+ .

To determine the correspondence between cluster ions and the neutral parent clusters, a scattering chamber filled with argon gas at 80 K is placed in the neutral beam path. A similar experiment with argon clusters is described in Ref. 6. The effective total cross section for the different ion signals is given in Fig. 1b.

The cross section of the He^+ signal is constant over the entire pressure range. We conclude that the He^+ ions are due to the unclustered He atoms in the neutral beam.

The cross section of the He^+ signal is constant for inlet pressures up to 500 torr. In this pressure range one neutral parent cluster for the He_2^+ ion exists.

From three arguments we conclude that the He_2^+ ions originate from neutral He_3 clusters for P_0 between

200 and 500 torr, which dissociate to He_2^+ in the ionizer.

Firstly, the intensity is proportional to P_0^3 . For the He_2 parents a proportionality of P_0^2 is expected.

Secondly, the ratio of the total cross sections for He^+ and He_2^+ is found to be as large as 1.95 ± 0.1 . It is difficult to reconcile this large ratio with a He_2 parent.⁶

Finally, the intensity of the trimers relative to the

FIG. 1. Intensity and cross section vs inlet pressure. Curves I, II, III, and IV correspond to ion masses 4, 8, 12, and 16, respectively.

monomers can be estimated⁶ assuming equilibrium in the source and assuming one bound state for a trimer. Good agreement is found with experimental values for a trimer parent; for a dimer parent, however, the estimated concentration is too large by an order of magnitude.

At pressures larger than 500 torr the cross section on He_2^+ rises owing to admixture of larger clusters in the beam and dissociative ionization. The He_3^+ cross section at $P_0 > 1000$ torr varies strongly with P_0 and is about 3.5 times larger than the He cross section. It seems impossible to link this behavior with a unique parent cluster.

In conclusion, our results agree with the prediction that there is no bound state for He_2 .

VI EQUILIBRIUM CALCULATIONS

VI 1 INTRODUCTION

In this chapter we present a calculation of dimer intensities obtained in supersonic expansions. There are two possible limiting considerations, the dimers observed are already present in the source, in thermodynamic equilibrium, and are accelerated in the expansion. Destruction during acceleration is neglected, as are processes leading to newly formed dimers. On the other hand one can apply a kinetic approach, where formation and destruction processes are followed throughout the expansion. The difficulty of this approach stems from the fact that the density, temperature and rate constants have to be known at all distances from the nozzle (ref. 1).

We first have adopted the simple point of view and have compared the measured dimer intensities (ref. 2, ch. III and IV) with the equilibrium concentration in the source. The comparison is performed under the assumption that the detection efficiency for dimers is twice the detection efficiency for monomers. The factor two stems from the enhanced ionization efficiency for the loosely bound van der Waals complex. Possible differences in detector transmission and multiplier yield are neglected. The source equilibrium calculation leads to agreement with observation within a factor three for Ar, Ne, and H_2 . For the diatomic species N_2 and NO the observed dependence of the dimer concentration on the stagnation pressure disagrees with the simple equilibrium theory, although the overall temperature dependence follows rather well the equilibrium predictions. In the last section we discuss the experimental evidence against the simple point of view that the dimers of the onset region are formed in the source already, under equilibrium conditions. Although this "source equilibrium theory" leads to semiquantitative agreement with the experimental results, the discussion indicates strongly that the observed dimers are formed downstream the nozzle. We are aware that neither a source- nor a downstream equilibrium approach gives an adequate description of the properties of a molecular beam which develops from a hydrodynamical flow into a free particle stream. Nevertheless, it appears that the source equilibrium gives the right dimer fraction within an order of magnitude, or even better for the noble systems. The larger discrepancy found for the diatomic systems, can be explained by downstream equilibrium, i.e. postfabrication. However, for Ne this leads to unphysically low forming temperatures of the dimer. In spite of this, equilibrium theory can be used as a predictor and helps to elucidate the dimer formation process.

We have not attempted to interpret our data on clusters heavier than dimers, because we know that the cluster ion signals do not correspond uniquely to neutral clusters. At the same time, occurrence of larger clusters destroys the

direct correspondence of the dimer ion signal and the neutral dimer, too.

As an exception, the He_2^+ signal is interpreted in the onset region as originating from a neutral He_3 (ref. 3, ch.V). In the next section an equilibrium calculation for a He trimer is given, too.

The starting point for all calculations is (ref.4)

$$n_1/n_1^i = z_1(T) / (z_1(T))^i \quad (\text{VI.1})$$

Here n_1 (n_2) stands for the number density of the monomer (dimer), $z_1(T) = Z_1(T,V)/V$ ($z_2(T) = Z_2(T,V)/V$) where $Z_1(T,V)$ ($Z_2(T,V)$) stands for the corresponding one particle partition function at temperature T ; V is the volume occupied by the gas. The equation is based upon „chemical” equilibrium between monomers and dimers; implicetly it is assumed that the mixture of monomers and dimers can be treated as a mixture of two perfect gases. Eq. VI.1 implies that n_2/n_1^2 is a function of temperature only. Thus, n_2 is proportional to the squared source pressure P_0^2 in the limit of low dimer concentration. Experimentally we found this pressure dependence for Ar_2 , Ne_2 , and $(\text{H}_2)_2$ in the beam (ch. III,IV).

For mixed dimers one derives with $K = n_2/n_a n_b$

$$K = \left[\frac{h^2 (m_a + m_b)}{2\pi kT m_a m_b} \right]^{3/2} \left[\sum_{v,j} (2j+1) \exp(-\epsilon_{v,j}/kT) \right] \left[\frac{1}{Z_{\text{rot},a}} \sum_{j_a} (2j_a+1) \exp \{ -j_a \cdot (j_a+1) \cdot B_a/kT \} \right] \left[\frac{1}{Z_{\text{rot},b}} \sum_{j_b} (2j_b+1) \exp \{ -j_b \cdot (j_b+1) \cdot B_b/kT \} \right] \quad (\text{IV.2})$$

The first factor on the right hand side represents the translational part of the partition function; the second factor contains the allowed dimer vib-rot-levels $\epsilon_{v,j}$; the third and fourth factor reflect the rotation of the constituent monomers. If other degrees of freedom are thermally excited, like the low lying electronic level of NO, extra factors of similar structure have to be added to the right hand side of eq. VI.2.

The summations have to be performed under the restriction

$$\epsilon_{v,j} + j_a \cdot (j_a + 1) \cdot B_a + j_b \cdot (j_b + 1) \cdot B_b < 0 \quad (\text{VI.3})$$

In eq. VI.2 m_a and m_b stand for the mass of the constituent monomers, B_a and B_b for their rotational constants, with corresponding quantum numbers j_a and j_b . It is assumed that the constituents can rotate freely (ref.5), and that their rotational states do not affect the dimer levels $\epsilon_{v,j}$. In the high temperature limit the rotational partition functions of both constituents $Z_{\text{rot},a}$ and $Z_{\text{rot},b}$ are equal to kT/B_a and kT/B_b , respectively. Except for H_2 , this high temperature limit is applicable to the description of our experiments for diatomic molecules. If $a = b$, eq. VI.2 reduces to a special case of eq. VI.1.

For the monoatomic systems the third and fourth factor are equal to unity. In that case the second factor has been evaluated semiclassically (ref. 6). One obtains for a Lennard Jones 12-6 interaction potential and for $kT > .5\epsilon$ (ref. 7)

$$n_2 / n_1^2 = 1.78 R_m^3 (kT/\epsilon)^{-1.5} G(Tk_0/\epsilon) \quad (\text{VI.4})$$

with $G(x) = 1 + .254/x + .057/x^2 + .0107/x^3$; ϵ and R_m represent the well depth and the position of the potential minimum.

In general, eq. VI.2 must be calculated numerically, because of the coupled summations due to eq. VI.3.

VI.2 EQUILIBRIUM THEORY FOR THE DIMER FRACTION OF INERT GAS SYSTEMS

In fig. VI.1, $\exp(\epsilon_{0,0}/kT)$ times the internal partition function $Z_{2,\text{int}}$ is given for Ar_2 , as a function of temperature, with $Z_{2,\text{int}} = \sum \exp(-\epsilon_{v,j}/kT)$. Because of symmetry only even values of j are taken into account in $Z_{2,\text{int}}$ (ref. 8). The steep increase at low temperatures reflects the exponential $\exp(\epsilon_{0,0}/kT)$. At high temperatures, $Z_{2,\text{int}}$ levels off because all stable states become occupied with equal probability.

Fig. VI.1. The internal partition function for Ar_2 , $Z_{2,\text{int}}$ multiplied by $\exp(\epsilon_{0,0}/kT)$, vs. temperature.

For Ar_2 the energy levels $\epsilon_{v,j}$, are calculated using spectroscopical constants given by Docken and Schafer (ref. 9), who determined the constants for an interaction potential of Ar_2 , obtained from differential cross section measurements by Pearson et al. (ref. 10). The level scheme is in agreement with UV absorption measurements of Tanaka and Yoshino (ref. 11), as discussed by LeRoy (ref. 12).

For Ne_2 similarly spectroscopical constants from Tanaka et al. (ref. 13) have been used. For $(\text{H}_2)_2$ the energy levels are calculated from a Lennard Jones 12-6 potential (ref. 14). Similarly, we could have used the high pressure infrared absorption data of Watanabe and Welsh (ref. 15), as analysed by Gordon and Cashion (ref. 16). Both level schemes yield practically indistinguishable partition functions.

The energy levels used are tabulated in appendix A1.

In all cases metastable dimers are neglected (eq. VI.3). They are assumed to dissociate before or during detection.

Mixed dimers of the Ne isotopes are observed, i.e. $^{20}\text{Ne}^{22}\text{Ne}$. From statistical symmetry arguments (ref. 8) their relative abundance compared to $^{20}\text{Ne}_2$ is expected to be twice the relative abundance of ^{22}Ne in ^{20}Ne . This is confirmed by experiment.

When calculating the partition function the ortho-para species of H_2 have been taken into account. Above 100 K higher rotational states of H_2 become populated. Because the rotational energy of an excited H_2 molecule exceeds the binding energy of a dimer by an order of magnitude, we discard the excited molecules in eq. VI.2 according to eq. VI.3.

Fig. VI.2 The equilibrium constant K_0 vs. temperature for Ar (a) and Ne (b). Also shown are the values for K_{obs} at different source temperatures. The open circles represent the values for K_0 from eq. VI.4.

Fig. VI.3. The equilibrium constant K_0 vs. temperature for H_2 .

At temperature between 10 K and 100 K one finds $K_0 \sim T^{-3/2}$; K_0 falls off more rapidly above 100 K because of excitation of higher rotational states of the monomers. A single value for K_{obs} is given at each source temperature, in good agreement with K_0 .

In fig. VI.2 we compare the calculated K_0 with experimental values K_{obs} for Ar and Ne; $K_0 = n_2/n_1^2$ is taken at source temperature T_0 , $K_{\text{obs}} = (I_2/I_1)/2n_1$, where I_2/I_1 stands for the experimental ratio of dimer and monomer intensity (see ch. III and IV); $n_1 = P_0/kT_0$ is the number density of the monomer in the source at pressure P_0 and temperature T_0 ; the factor 2 compensates approximately for the larger detection efficiency of the dimer with respect to that of the monomer. Besides our own calculation of K_0 the semiclassical results of Stogryn and Hirschfelder (eq. VI.4) are displayed in fig. VI.2. The simple eq. VI.4, thus, yields good agreement for Ne and Ar.

We find $K_{\text{obs}} = 2 K_0$ for Ar and $K_{\text{obs}} \approx 3 K_0$ for Ne.

The calculated values of K_0 for H_2 are displayed in fig. VI.3, together with our experimental values K_{obs} , taken from ch. IV. The experimental values are lower than the calculated ones generally, $K_{\text{obs}} \approx 0.8 K_0$.

Possible formation of a stable He_2 (ref. 17,18) has become a much discussed question recently. If there exists a bound state at all, its energy would be $\epsilon_{0,0}/k = -0.1$ K, at maximum. In the calculation of K_0 this binding energy can be neglected compared to the thermal energy kT_0 ($T_0 = 7$ K used in our experiment, ch. V). In fig. VI.4 the calculated equilibrium constant K_0 is displayed. The temperature dependence is purely translational, $K_0 \approx T_0^{-1.5}$. The experimental results show no quadratic pressure dependence at all. Therefore, a range of experimental K_{obs} is shown in fig. VI.4; the values even at high pressures are far too low compared to K_0 .

In fig. VI.4 the result for a supposed He_3 is shown, too, $K_3 = n_3/n_1^3 \approx T^{-3}$.

Fig. VI.4. The equilibrium constant vs. temperature for the smallest He cluster. The left part of the figure corresponds to the dimer calculation with $K_0 \sim T^{-3/2}$. The experimental points K_{obs} are pressure dependent and far too low. The monomer density n_1 in the source is indicated in amagat. The right part corresponds to the trimer calculation, with $K_0 \sim T^{-3}$. The experimental $K_{3,\text{obs}}$, in fair agreement with K_3 , assume a single value for all source pressures of interest.

Again, a single bound state with negligible binding energy is assumed, in accordance with the theoretical prediction of ref. 19. Experimentally, the He_2^+ signal is proportional to the third power of the source pressure, P_0^3 . Therefore, all our $K_{3,\text{obs}}$ condense into one single point, if we take a He trimer as being responsible for the observed He_2^+ signal. Here, $K_{3,\text{obs}}$ is defined as $K_{3,\text{obs}} = (I_2/I_1)/3n_1^2$ with $n_1 = P_0/kT_0$. The experimental intensity ratio for He_2^+ and He^+ , I_2/I_1 , is divided by a factor 3 to compensate approximately for the larger ionization efficiency of the He trimer. The experimental $K_{3,\text{obs}}$ is in fair agreement with K_3 .

VI.3 EQUILIBRIUM THEORY FOR DIATOMIC SYSTEMS

For N_2 and NO three important features are observed, 1) the dimer intensity is more than a factor 10 lower compared to Ar, 2) the quantity K_{obs} is proportional to $T_0^{-\delta}$, with $\delta > 2$, whereas $\delta \simeq 1.7$ has been found for Ar, Ne, and H_2 , 3) K_{obs} does depend on the source pressure P_0 , whereas K_{obs} is pressure independent for Ar, Ne, and H_2 . All three properties can be explained from one single point of view, the rotational degree of freedom of the constituents of the dimer.

According to eq. VI.3 only those states are taken into account in the calculation of K_0 for which the sum of the rotational energies and of the end over end rotation does not exceed the binding energy for the different vibrational levels of the dimer.

The vibrational levels $\epsilon_{v,m}$ are approximated by a J.W.K.B. – calculation for a Lennard Jones 12-6 potential with ϵ and R_m taken from ref. 20. The vibrational levels used are tabulated in appendix A 1. For all vibrational levels the rotational constant of the dimer is taken at the equilibrium distance R_m , i.e. $B_v = \hbar^2/m_1 \cdot R_m^2$ (m_1 equals the monomer mass). The monomer rotational constant is taken from ref. 21.

The influence of these two approximations is tested for Ar, where Z_2 from the "exact" level scheme (ref. 9) is compared to Z_2 for the J.W.K.B. approximated level scheme for a Lennard Jones 12-6 potential, with parameters ϵ and R_m from ref. 20. The resulting partition function Z_2 is 40% lower for our approximation. If ϵ/k for the Lennard Jones potential is taken equal to 140.8 K (ref. 9) instead of $\epsilon/k = 124$ K (ref. 20), retaining a constant value of the reduced de Broglie wavelength $\Lambda^* = \hbar/R_m(m_1\epsilon)^{1/2}$, the difference between both partition functions becomes 15%. This remaining difference is entirely due to the choice of a single value for the dimer rotational constant B_v , which is too large for high vibrational levels (see appendix A1).

For N_2 we tested the dependence of Z_2 on the well depth ϵ , increasing $\epsilon/k = 91.5$ K of ref. 20 also by 13% with constant Λ^* ; an increase in Z_2 of 50% was found at maximum. We estimate, therefore, that K_0 , being calculated with ϵ and

R_m of ref. 20 could be 70% too small. In the following we will use this rather low value of K_0 only.

With the above mentioned assumptions we obtain values for K_0 which are two orders of magnitude lower than n_2/n_1^2 calculated according eq. VI.4. The resulting values are shown in fig. VI.5 for N_2 and NO respectively.

The tremendous influence of the rotational degree of freedom on the equilibrium constant K_0 is thus put into evidence.

Also displayed are values of K_{obs} for different densities $n_1 = P_0/kT_0$ (n_1 indicated in amagat). The discrepancy between K_{obs} and K_0 is larger than for Ar and Ne; $K_{obs} \simeq 10K_0$.

The general temperature dependence of K_{obs} is in reasonable agreement with the temperature dependence of K_0 , for instance for N_2 , $K_0 \simeq T^{-3.6}$, see fig. VI.5a.

The increase of K_{obs} with pressure indicates that the dimers are not prefabricated in the source under equilibrium conditions, otherwise K_{obs} must be pressure independent. We attribute the observed increase of K_{obs} with P_0 to formation of dimers downstream the nozzle and to rotational cooling in the

Fig. VI.5. The equilibrium constant K_0 vs. temperature for N_2 (a) and NO (b).

The solid lines represent the calculated K_0 . The stronger temperature dependence here, compared to fig. VI.2, is caused by the monomer rotational degree of freedom. The values of K_{obs} are given for different n_1 , the monomer density in the source, indicated in amagat units, at four source temperatures. Because the dimer intensity is not proportional to P_0^2 , K_{obs} assumes different values at different $P_0 = n_1 kT_0$, for each T_0 .

expanding beam. This point will be discussed in the next section. Nevertheless, the equilibrium theory is apparently capable to explain the gross features of our observations.

VI.4. DISCUSSION

The agreement between source equilibrium calculations and the experimental values for n_2/n_1^2 is satisfying for Ar and Ne. The remaining discrepancy amounts to $K_{\text{obs}} = 2K_0$ for Ar, and $K_{\text{obs}} \approx 3K_0$ for Ne. For dimers Milne and Greene (ref. 1) have introduced an extra mass separation factor (a factor 2) to deal with this discrepancy for Ar. We have investigated this mass separation on a 1:3 mixture of Ar and Ne; no enhancement of Ar was found. This does not entirely exclude mass separation for our actual 1:100 mixture of dimers and monomers, but we do not believe in the magnitude of the effect assumed in ref. 1.

Fig. VI.6. K_f/K_0 vs. temperature for N_2 (a) and NO (b).

The ratio K_f/K_0 stands for the increase of the equilibrium dimer fraction in the isentropically expanding beam with respect to the dimer fraction in the source. The arrows on the abscissa indicate the four experimental source temperatures. As the expansion proceeds the beam temperature becomes lower and the dimer fraction increases as shown. The experimental results K_{obs}/K_0 are indicated by the open circles and labeled by the corresponding monomer densities in the source. From these ratios one infers formation temperatures K_f which describe the observed dimer fractions, $30\text{ K} < T_f < 100\text{ K}$. For N_2 the ratio K_f/K_0 , calculated according to eq. VI.6 with $\alpha = 7/5$, is indicated by the dotted line.

On the other hand, it is clear from fig. IV.1 and IV.2 that the monomer intensity departs from the extrapolated straight line $\sim P_0^1$ of the onset region, at such pressures where the dimers are observed. The origin of this deficiency may be sought in a mass separation in the expanding beam. We have corrected for this deficiency, using the extrapolated straight line values. The correction on K_{obs} has negligible influence for Ar and Ne. For N_2 and NO it amounts to a factor 1.5 at maximum; nevertheless, it does not bring the K_{obs} and K_0 into as close an agreement as found e.g. for Ar.

However, it is not necessary that the dimers observed are formed in the source under equilibrium conditions, only. A cooling of all degrees of freedom for monomers in a nozzle expansion has been observed many times (ref. 22). If dimers are formed downstream the nozzle and if the beam temperature has dropped before the dimer formation ends, one may expect dimer fraction quite different from the equilibrium value in the source. Hagena (ref. 7) has discussed such a "downstream equilibrium" and gives the variation of the equilibrium dimer fraction with T_f , the temperature downstream the nozzle which determines the finally observed dimer fraction.

The expansion from T_0 to T_f is assumed to be isentropic. For Ar and Ne one may use eq. VI.4 to obtain

$$K_f = K_0 \cdot (T_f/T_0)^{(5-3\kappa)/(2\kappa-2)} \cdot G(kT_f/\epsilon) / G(kT_0/\epsilon), \quad (\text{VI.6})$$

where κ is the specific heat ratio and $K_f = [n_2/n_1]_{T_f} \cdot kT_0/2P_0$. In the case of noble gases $\kappa = 5/3$ and the second factor on the right hand side is equal to unity. As $G(x)$ is only a slowly varying function of x for $x > .5$, the dimer fraction is rather insensitive to T_f . To achieve agreement between K_{obs} and K_f we must assume a final temperature T_f , $T_f \simeq 60\text{K}$ for Ar, for all T_0 between 120K and 300 K, independent of P_0 . For Ne the downstream equilibrium would lead to $T_f < 20\text{K}$; for this low T_f our basic assumptions are not longer valid.

For Ar, Ne and H_2 the close agreement between K_{obs} and K_f is caused by the rather weak dependence of the dimer fraction on T_f ; it does not prove that the observed dimers are already formed in the source.

For H_2 good agreement is found between K_0 and K_{obs} . This stems from the near independency of K_f on T_f for $T_f > 10\text{K}$, due to the small binding energy of the H_2 dimer levels. Thus, any T_f with $10\text{K} < T_f < T_0$ would fit to our measurements.

For the diatomic systems N_2 and NO the discussion of the experimental results in the light of a source equilibrium theory is problematic, because the dimer intensity is not found to be proportional to P_0^2 . The value of K_{obs} changes about a factor 2 for N_2 (a factor 5 for NO) at fixed T_0 , if the pressure P_0 is varied from the detection limit up to P_1 (see ch. III and IV). A large spread of experimental points is caused by the pressure dependence, $K_{\text{obs}} \sim P_0^{.5}$ for N_2 and $K_{\text{obs}} \sim P_0^{.8}$ for NO.

As in the case of Ar and Ne, we have investigated the consequences of dimer formation downstream the nozzle. The new element for the diatomic molecules is the strong influence of the rotational cooling on Z_2 in eq. VI.2. Using eq. VI.2 one can derive a relation for K_f for diatomic systems analogously to eq. VI.6. In fig. VI.6 calculated values for K_f/K_0 are given for different source temperatures. Hagen, who has not explicitly taken into account the rotational cooling, finds a behaviour completely different from our calculations for N_2 (see fig. VI.6). For NO, the cooling of the electronic degree of freedom must also be taken into account. The slightly larger temperature and pressure dependence of K_{obs} , as displayed in fig. VI.6 is attributed to the electronic cooling.

In contrast to the noble systems the influence of T_f on the dimer fraction is very pronounced in the case of N_2 and NO due to the presence of internal degrees of freedom. The observed pressure dependence of K_{obs} , therefore indicates strongly that the dimers are formed downstream the nozzle, at temperatures T_f between 30 K and 100 K (see fig. VI.6).

VII MIXED DIMERS

VII.1 INTRODUCTION

Continuing our investigation of dimer production (ref 1) we have tried to detect mixed dimers in nozzle beams of mixtures, NeAr and HeNe dimers were observed with sufficient intensity to determine the total collision cross section. A similar attempt for H_2Ar was partially hampered by the circumstance that the corresponding HAr^+ ion must be detected on the wing of the thousand times larger Ar^+ peak. Our search for H_2He , H_2Ne and HeAr dimers was not successful, due to masking ion peaks, H_s^+ for HHe^+ , $^{21}\text{Ne}^+$ for H^{20}Ne^+ , and CO_2^+ for HeAr^+ .

For the Ne-Ar mixture (3 Ne : 1 Ar in the source) we observe an optimum NeAr^+ signal of about 0.1% of the Ar^+ signal with a signal to noise ratio $S/N = 30$, at a time constant $\tau = 1$ sec. A similar result is obtained for the He-Ne mixture. At the moment these optimum signals seem too small for electric beam resonance measurements, which appear interesting in view of recent discussions of the electric dipole moment of these mixed inert gas dimers (ref 2).

The existence of an H_2He dimer is questionable (ref 3). The situation can be compared to that of the He dimer. Our results do not throw new light on this problem.

A positive aspect of the mixed clusters and their mass spectrometric detection is the low probability for fragmentation of larger clusters to the mixed dimer ion. For instance, using the Ne-Ar mixture, signals of Ar_1^+ and Ar_4^+ ions are found, but no signals of NeAr_2^+ ions. Even conceding that neutral NeAr_2 is present in the beam, NeAr^+ will be formed as fragment ion with smaller probability than Ar_2^+ . In complete agreement herewith we observe a constant collision cross section for the NeAr^+ parent up to pressures substantially higher than those at which the $\text{Ar}_2^-/\text{Ar}_2^+$ correspondence breaks down, i.e. P_1 (sect VII 3), at these high pressures the NeAr^+ signal goes through a maximum. For HeNe^+ a constant collision cross section is observed up to pressures where the HeNe^+ signal has dropped already to 1/3 of its maximum value.

As will be shown in sect VII 4 the observed mixed dimer intensities can be fairly well predicted from a source equilibrium calculation.

Concerning the production of pure dimers from gas mixtures, e.g. Ar_2 from the Ne-Ar mixture, we observe a significant increase through the presence of the lighter gas compared to the dimer intensity from pure gases, at the same partial pressure and temperature in the source. This increase points definitively in the direction of dimer formation downstream the nozzle, where, due to the extra acceleration of the beam molecules by the light carrier gas, the formation temperature T_f is lower than for pure gas jets, see sect VII 4. Similar observations have been reported in ref 4.

In fig. VII.1, 2a and 2b the intensities are displayed for the mixed gases as a function of the source pressure P_0 . The mixtures have been prepared by us from commercial pure gases; we have used 1:3 mixtures of Ar in Ne, Ne in He and Ar in H_2 .

The monomer signals nearly coincide for Ne-Ar and He-Ne mixtures.

When the difference in detection efficiency is taken into account (see appendix A 2) we find no enhancement of the heavier monomer in the beam. On the other hand, for the H_2 -Ar mixture with its large mass difference between the components, an order of magnitude less H_2 is measured with respect to Ar. This cannot be explained by a difference in detection efficiency. The light carrier gas is lost from the central beam by collisions with the heavier component (ref. 4). As soon as the Ar_2 signal appears, the H_2 monomer signal becomes practically independent of P_0 , presumably due to increasing losses caused by the Ar dimer formation process. Energy is liberated in the dimer formation process; corresponding linear momentum is mainly imparted to the lighter component of the mixture.

For a pure Ar monomer beam a signal from Ar^{++} ions is observed, of about 10% of the Ar^+ signal, at an electron bombardment energy of 130 eV. In fig. VII. 1 the intensity of Ne^+ is corrected for this Ar^{++} signal (about 10% decrease).

Fig. VII.1. Intensity vs. reduced pressure for Ne-Ar.

The Ne^+ intensity (Ia, displayed multiplied by a factor 10) nearly coincides with the Ar^+ intensity (Ib). Both monomer intensities are proportional to $P_0^{\alpha_1}$ at low pressures, with $\alpha_1 = 1.0 \pm .1$. For the Ar_2^+ (II) and $NeAr^+$ (III) intensity similar proportionalities hold with exponents $\alpha_2 = 2.5 \pm .2$ and $\alpha_3 = 1.6 \pm .2$, respectively. The intensities are measured at different source temperatures, $T_0 = 296$ K (\bullet), $T_0 = 190$ K (\blacktriangle), $T_0 = 148$ K (\triangle), and $T_0 = 108$ K (\circ). The abscissa gives the true pressure in torr for $T_0 = 190$ K. At other temperatures reduction factors P_0/P_{red} are applied for each ion mass (table VII.1.) The shaded area indicates the reduced pressure \tilde{P}_L at which the Ar_2 signal becomes contaminated by fragments of larger clusters.

Fig.VII.2. Intensity vs. source pressure for He-Ne (a) and H_2 -Ar (b).

For He-Ne (at source temperature $T_0 = 31$ K) the intensities are shown of the ions He^+ (Ia), $^{20}\text{Ne}^+$ (Ib), $^{20}\text{Ne}_2^+$ (IIa), $^{20}\text{Ne}^{22}\text{Ne}^+$ (IIb); at low pressures the ion signals are proportional to $P_0^{\alpha_m}$, with $\alpha_m \approx 1$ (I), $\alpha_2 = 2.3 \pm .2$ and $\alpha_3 = 1.5 \pm .2$ (III). Also shown are the intensities for Ne_3^+ (IV) and Ne_4^+ (V). At the pressure P_L fragment ions of larger clusters start to contribute to the Ne_2^+ signal. For H_2 -Ar at source temperature $T_0 = 173$ K, the intensities are shown of H_2^+ (Ia), Ar^+ (Ib), Ar_2^+ (II), and HAr^+ (III). At low pressures the ion signals rise proportionally to $P_0^{\alpha_m}$, with $\alpha_{1a} = 1. \pm .2$, $\alpha_{1b} = 1. \pm .1$, $\alpha_2 = 2.3 \pm .1$, and $\alpha_3 = 1.5 \pm .2$, respectively.

In fig. VII.1 the pressure scale is the true one for $T_0 = 190$ K; for other temperatures the pressure scale is reduced for each ion signal by the factors P_0/P_{red} , given in table VII.1.

The $^{20}\text{Ne}^{40}\text{Ar}^+$ ion signal could be contaminated by Ar_3^{++} ions, possessing the same e/m ratio. However, for a pure Ar beam no Ar_3^{++} has been found; therefore we exclude this possibility.

We have not found signals of $^{22}\text{Ne}^{40}\text{Ar}^+$ or $^4\text{He}^{22}\text{Ne}^+$ ions; their intensity can be estimated to be an order of magnitude lower than that observed for $^{20}\text{Ne}^{40}\text{Ar}^+$ and $^4\text{He}^{20}\text{Ne}^+$ ions; this is beneath our detection limit.

Our mass spectrometer has a limited suppression of neighbouring mass peaks; for a pure Ar beam about .03% of the Ar^+ signal is measured at the mass-setting for HAr^+ . The mixed dimer signal in the case of H_2 -Ar, HAr^+ , must be detected on the wing of a thousand times larger $^{40}\text{Ar}^+$ monomer peak. Therefore, the intensities of fig.VII.2b should be taken with some reserve. However, the scattering results of the next section prove that a mixed dimer signal is present. No attempt with a D_2 -Ar mixture has been made yet.

Dimers of the heavier component in the mixture are detected. In contrast to the case of pure gases, their intensity is proportional to $P_0^{\alpha_2}$, with α_2 larger than 2 (see caption of fig. VII. 1 and 2); for pure gases $\alpha_2 = 2$ has been found (ref. 1, ch. III and IV). At the same source temperature and partial source pressure the dimer intensity from the mixture has increased with respect to that of the pure gas. For a discussion see sect. VII.4.

The monomer intensities are about proportional to P_0 at low pressures; the mixed dimer signals have pressure exponents α_1 smaller than 2. The exact values are given in the captions.

TABLE VII.1

| | | T_0 (K) | | | | | | β_1 |
|-----------------------------------|-------|-----------|-----------|-----|----------|-----|-----|-----------|
| | | 108 | 148 | 190 | 296 | 120 | 210 | |
| Ne ⁺ , Ar ⁺ | (I) | .65 ± .1 | .8 ± .1 | 1 | 1.5 ± .1 | .7 | 1.1 | .85 ± .1 |
| Ar ₂ ⁺ | (II) | .35 ± .02 | .55 ± .03 | 1 | 2.1 ± .1 | .4 | 1.4 | 2.1 ± .1 |
| NeAr ⁺ | (III) | .47 ± .05 | .65 ± .07 | 1 | 1.6 ± .1 | .5 | 1.2 | 1.6 ± .1 |

Table VII. 1 Reduction factors $f = P_0 / P_{red}$ for Ne-Ar

The values for f at $T_0 = 120$ K and $T_0 = 210$ K have been interpolated, using the approximation $f \propto T_0^{\beta_1}$. The values for β_1 are given in the last column.

VII 3 SCATTERING

In fig. VII.3 the total collision cross sections vs. reduced source pressure are displayed relative to the Ar monomer cross section, for the different ion signals of the Ne-Ar mixture; He was used as scattering partner. The cross sections at three different source temperatures $T_0 = 120, 210$ and 296 K are collected in one figure by a similar reduction of the pressure scale as for the intensities; for $T_0 = 120$ and 210 K interpolated reduction factors are used, see table VII.1. The experimental cross sections are corrected for the finite angular resolution following ref. 5.

At low pressures all cross sections are independent of P_0 , indicating a direct correspondence between ions and neutrals.

The ratio of the cross section $\sigma_{Ar} / \sigma_{Ar}$ is found to be $1.52 \pm .02$, with He as target molecule. The cross section of the mixed dimer σ_{NeAr} , is seen to be $(1.61 \pm .02)$ times $\frac{1}{2}(\sigma_{Ar} + \sigma_{Ne})$.

With Ar as scattering partner we find for $\sigma_{Ar} / \sigma_{Ar} = 1.36 \pm .02$ and $\sigma_{NeAr} = (1.45 \pm .02) \cdot \frac{1}{2}(\sigma_{Ar} + \sigma_{Ne})$ at a source temperature $T_0 = 210$ K.

For the Ar_2^+ signal a source pressure \tilde{P}_1 can be defined in fig. VII.3; at \tilde{P}_L the cross section starts to rise above its constant low pressure value. The pressure P_L is 500 torr for $T_0 = 120$ K, 1800 torr for $T_0 = 210$ K; for $T_0 = 294$ K no rise of the Ar_2^+ cross section is yet observed, i.e. $P_1 > 4000$ torr. Indicated in fig. VII.1 and 3 is \tilde{P}_1 , obtained from the aforementioned P_L values and the reduction factors of table VII.1 for the Ar_2^+ signal.

The partial pressure for Ar at P_L is roughly equal to $\frac{1}{2} P_L$ found for pure Ar (cf. ch. III), in accordance with ref.4.

In fig. VII.4a and 4b the cross section for the He-Ne and the H_2 -Ar mixture are given each for one source temperature ($T_0 = 31$ K and $T_0 = 90$ K, respectively), and one scattering partner (He and Kr, respectively). Here too, the cross sections displayed are corrected for the finite angular resolution. For the He^+ , Ne^+ , and $HeNe^+$ signal the cross sections are again independent of P_0 . From the constant behaviour of σ_{HeNe} we infer that no larger mixed clusters, if present at all, contribute to the $HeNe^+$ signal. One obtains $\sigma_{HeNe} = (1.83 \pm .06) \cdot \frac{1}{2} (\sigma_{Ne} + \sigma_{He})$ with He as scattering partner.

At $P_0 < 300$ torr the Ne_2 cross section is measured, yielding $\sigma_{Ne_2} / \sigma_{Ne} = 1.75 \pm .06$. Here, the partial Ne pressure at $P_L = 300$ torr is about equal to P_L in the pure Ne case of ch. IV. For $P_0 > P_L$ the dimer ion cross section rises to values near to those of the cross section for the larger cluster ions, Ne_3^+ and Ne_4^+ .

In order to obtain larger mixed dimer signals and to reduce the influence of the limited mass separation (see sect. VII.2) we have used a different source temperature and gas mixture in the measurement of the cross sections of H_2 -Ar ($T_0 = 90$ K vs. $T_0 = 173$ K used for the intensities in fig. VII.2b, and a 8:1 mixture vs. 3:1). As in fig. VII.2b the H_2^+ ion signal assumes a nearly constant value over the pressure range where dimer signals are present; this constant signal is about 10% of the Ar^+ signal (vs. 1.5-3% in fig. VII.2b). At a source

caption to fig VII.3

Fig. VII.3. Apparent cross section vs. reduced pressure for the Ne-Ar mixture with He as scattering gas. The cross sections are displayed relative to the Ar monomer cross section; they are measured at source temperatures $T_0 = 296$ K (▲), $T_0 = 210$ K (●), and $T_0 = 120$ K (○); for the reduction of the pressure scale interpolated P_0/P_{red} values are used, see table VII.1. From $P_{red} < \bar{P}_L$ the Ar_2 cross section is obtained. For NeAr the results are independent of pressure over the whole pressure range.

Fig. VII.4 Apparent cross section vs. source pressure P_0 , (a) for a 3:1 He-Ne and (b) for a 8:1 H_2 -Ar mixture with He and Kr as target gas, at temperatures $T_0 = 31$ K and 90 K, respectively. In the left part the He^+ (Ia), Ne^+ (Ib), and $HeNe^+$ (III) attenuations correspond for all pressures, those for Ne_2^+ (II) only for $P_0 < P_L$, to cross sections of well defined neutral particles. In the right part the attenuations of H_2^+ (Ia), Ar^+ (Ib), Ar_2^+ (II) and HAr^+ (III) correspond each to a unique neutral parent for $P_0 < P_L = 10^3$ torr. At pressure $P_0 > P_L$ larger clusters contribute to both dimer signals.

pressure $P_0 = 1000$ torr both the Ar^+ and the HAr^+ ion signal go through a maximum; the maximum Ar_2 and HAr signal are 10% and 2% of the Ar^+ signal, respectively. The signal to noise ratio of the HAr^+ ion signal here, is 50, at a time constant of 1 sec.

From fig. VII.4b one infers a constant cross section for all ion signals at source pressures $P_0 < 1000$ torr. One obtains $\sigma_{Ar_2} / \sigma_{Ar} = 1.35 \pm .02$ and $\sigma_{H_2Ar} = (1.45 \pm .02) \cdot \frac{1}{2} (\sigma_{H_2} + \sigma_{Ar})$. Due to the contribution of the Ar^+ signal to the HAr^+ signal as explained in the introduction, we present the cross section of the H_2Ar dimer as a lower limit; the value is estimated to be too low by 2% at maximum.

At $P_0 > 1000$ torr the cross section for the Ar_2^+ and the HAr^+ signal starts to rise, due to the admixture of larger clusters. For Ar_2^+ this rise has been observed earlier (ref. 1a); for HAr^+ this rise is the only indication in our investigation to the existence of larger mixed clusters. At the same pressures, signals of H_3^+ ions are detected too.

The decrease of the monomer cross section for Ar has been dealt with in an earlier paper (ref. 1a).

For a comparison of the observed mixed dimer concentration of NeAr and the equilibrium concentration in the source we calculated the partition function Z_{mix} ; the vibrational energy have been calculated by us in the J.W.K.B. approximation, using ϵ and R_m values for the Lennard-Jones 12-6 potential from ref. 6, see appendix A1. The rotational constant B has been taken at the equilibrium position of the two atoms, for all 5 vibrational levels. The resulting partition function is estimated to give values 40% too small. The estimate is based on similar Ar_2 results (sect. VI.2). From the partition functions the equilibrium constant $K_0 = n_{\text{NeAr}} / n_{\text{Ne}} \cdot n_{\text{Ar}}$ is calculated as a function of the source temperature T_0 .

The experimental intensity ratio $I_{\text{NeAr}} / I_{\text{Ar}}$ is divided by 1.25 to compensate for the increased detection efficiency, and by the calculated neon density in the source, to obtain values for K_{obs} . For a fixed source temperature T_0 the intensity ratios are used only for pressures lower than P_0 , where the intensities reach their maxima (onset region). The resulting K_{obs} values are independent of the source pressure P_0 to within 10%. Therefore in fig. VII.7 only one point is given for each T_0 . We find $K_{\text{obs}} \simeq K_0$.

Similarly, we compared the Ar_2 concentration with the data for pure Ar

caption to fig. VII.5

Fig. VII.5 Equilibrium constant vs. temperature.

In the left part (a) the calculated curve K_0 is taken from sect. VI.2; the dots indicate the values for K_{obs} for Ar_2 from pure Ar (see fig. VI.2). The open circles indicate the values for K_{obs} for Ar_2 from the Ne-Ar mixture; n_i stands for the partial Ar density in the source (in amagat). In the right part the dots correspond to the values of K_{obs} for NeAr, which are in good agreement with K_0 (solid line).

from sect. VI.2, for pressures lower than P_l (see sect. VII.3). In the onset region the Ar_2^+ intensity is proportional to $P_0^{2.5}$; consequently, the values for K_{obs} are pressure dependent. In fig. VII.7 we give the values at different pressures, as indicated in the caption.

With respect to sect. VI.2 an increase of the experimental dimer concentration is found, which amounts to a factor 4, at maximum. Thus, K_{obs} is pressure dependent and 4 to 8 times larger than $K_0 = n_{\text{Ar}}/n_{\text{Ar}}^2$. Both effects are attributed to an extra cooling during expansion due to the presence of the lighter Ne. They indicate strongly that the dimers observed are produced during the expansion.

The fact that $K_{\text{obs}} \simeq K_0$ for NeAr, while large discrepancies occur for Ar_2 from the Ne-Ar gas mixture, can be explained as follows; the NeAr dimer fraction is rather independent of the temperature T_f , whereas for Ar_2 , with its two times larger potential minimum ϵ , this temperature T_f forms a very critical parameter. As discussed in sect. VI.4, the dimers are assumed to be formed downstream the nozzle at an effective equilibrium temperature $T_f < T_0$. Then $K_{\text{obs}} = K_f$, with

$$K_f = K_0 \frac{G(kT_f/\epsilon)}{G(kT_0/\epsilon)}$$

(sect. VI.4), where

$$G(x) = 1 + .254/x + .057/x^2 + .0107/x^3$$

is a function weakly dependent on x for $x \geq .5$.

For Ar_2 with its large ϵ -value the condition $x \geq .5$ is not fulfilled.

For the other mixed dimer H_2Ar and HeNe the results in general are similar and give no new insights; they do not yet justify an extensive calculation.

VIII MEASUREMENTS OF TOTAL COLLISION CROSS SECTION FOR DIMERS OF SIMPLE ATOMS AND MOLECULES IN THE GLORY- AND TRANSITION REGION.

VIII.1. INTRODUCTION.

In this communication we present a survey of total collision cross sections for van der Waals dimers of the inert gases Ar and Ne, the molecules H_2 , N_2 , NO, O_2 , CO_2 , and C_2H_4 , and for mixed dimers NeAr, HeNe and H_2 Ar. Most of the measurements of the dimer cross sections, σ_2 , relative to the corresponding monomer cross section, σ_1 , have been described before (ref. 1, 2, 3, ch. III, IV and VII). For a complete review, we have added the results for the He trimer (ref. 4, ch. V) and our unpublished results for the CO_2 and C_2H_4 dimers.

The dimers are produced in a nozzle beam and are detected by a mass spectrometer. The total collision cross section is determined from the attenuation of the beam by a target gas (Ar, Kr or He) in a scattering chamber (at 80K for Ar and He, 200K for Kr).

In fig. VIII.1 all ratios σ_2/σ_1 are collected and plotted vs. the reduced velocity $v_{red} = \hbar v/\epsilon R_m$. For mixed dimers the average value of both monomer cross sections is taken instead of σ_1 . The systems investigated are summarized in table VIII.1. The relative scattering velocity v is calculated by $v = (v_1^2 + \alpha_s^2)^{1/2}$ (cf. ref. 5); for the beam velocity v_1 full isentropic expansion is assumed (ref. 6); the velocity α_s is the thermal velocity of the target molecules in the scattering chamber. The f.w.h.m. spread in relative velocity is about equal to α_s .

The values for ϵ and R_m are taken from a Lennard Jones interaction potential of monomer (the heavier monomer for mixed dimers) and target molecules (ref. 7, see table VIII.1).

A correction to σ_2/σ_1 for the finite angular resolution is applied following ref. 8. The absolute value of the total cross section, required for the calculation of the correction, is determined from Swedenburg et al. (ref. 9) and Gengenbach et al. (ref. 10), and our relative measurements.

The correction formula of ref.8 has been derived under the assumptions $v_1/\alpha_s \geq 2$ and $\sigma_1 \propto v^{-2/5}$. Consequently, this correction is uncertain for He as target molecule. Due to lack of a better procedure, it is applied, nevertheless. The fact that the experimental results taken with He in the scatterbox do not show any striking deviation in fig. VIII.1 has helped us to subdue our scruples. In table VIII.1 both measured and corrected values of σ_2/σ_1 are given.

Because of the large spread in relative velocity we do not observe a glory type velocity dependence of σ_2/σ_1 . The monomers and dimers in the beam have essentially the same velocity. The spread in relative velocity is practically entirely due to the thermal velocity of the target gas α_s ; the correction factor for the total collision cross section to deal with this spread is equal for both monomers and dimers, leaving the ratio σ_2/σ_1 unchanged.

Table VIII 1 Summary of all dimer to monomer cross section ratios investigated. In the second column the symbols are given which are used in fig. VIII 1 for the different systems. In column σ_2/σ_1 (eff) the measured ratio of dimer to monomer cross section is displayed. These values have to be multiplied by the correction factor ΔC_γ and σ_2/σ_1 (corr) to obtain the corrected σ_2/σ_1 . For the bracketed values of ΔC_γ and σ_2/σ_1 (corr) the correction is uncertain. The column $\hbar v/\epsilon R_m$ gives the reduced velocity with ϵR_m values for a from ref. 7a, b from ref. 7b, c from ref. 7c, d from ref. 7d, e from ref. 10 and f from combination rules applied to the e and R_m values from ref. 7a.

Fig.VIII.1 shows that at low reduced velocities $v_{red} < .4$, the ratio σ_2/σ_1 assumes values between 1.32 and 1.45, it rises at larger reduced velocities and approaches a value 2 for $v_{red} > 1$. All σ_2/σ_1 results for the large variety of very different systems fall on one single curve in good approximation. Only He forms a striking exception.

For $v_{red} < .4$ the monomer cross section σ_1 is dominated by attractive forces between monomer and target. With an interaction potential V , $V(r) = -C_{6,m}/r^6$, one has $\sigma_1 = 8.083(C_6/\hbar v)^{2/5}$ (ref.11). When we assume that a similar potential, $-C_{6,d}/r^6$, describes the interaction between dimer and target molecule the ratio σ_2/σ_1 varying from 1.32 to 1.45 points to $C_{6,d}/C_{6,m}$ between 2.0 and 2.5.

Indicated in fig.VIII.1 are the approximate reduced velocities at which glory maxima (integer N) or glory minima (half integer N) would occur in the monomer total collision cross section (ref.12). It is improbable that a loosely bound dimer will survive collisions at glory impact parameters; an eventual glory structure in σ_2/σ_1 will be predominantly due to glories of σ_1 .

No distinct glory structure is observed in σ_2/σ_1 ; the absence can be explained by the velocity averaging in our experimental set up, by the achieved accuracy for σ_2 and the smallness of the glory amplitude. For the H_2 -beam and Ar as target, however, a slight variation of σ_2/σ_1 at $.23 < v_{red} < .58$ is observed, which may be attributed to the $N = 1$ glory of σ_1 .

For $v_{red} > .8$ (transition region) the repulsive forces determine the monomer cross section. At high reduced velocities, where the "collision diameter" of the constituent monomer becomes comparable to or smaller than the mean distance in the dimer, we expect $\sigma_2/\sigma_1 = 2$.

The ratio σ_2/σ_1 for NO is slightly but significantly lower than for most other systems. This might be attributed to a strong interaction (of chemical nature or due to dipole-dipole forces) between the two NO molecules in the dimer, which decreases the size of the dimer (ref. 13).

A special case is formed by He; for the smallest He-cluster we find a cross section which is 1.95 times the monomer cross section, although the velocity is well within the $v^{-2/5}$ -region, $v_{red} = .23$ (Ar as target). This high ratio is one of the arguments by which we have concluded that the smallest cluster observed for He must be a trimer (ref.4).

APPENDIX

A1. VIBROTOR LEVELS OF DIMERS

In table A1.1 the vibrational levels $\epsilon_{v,0}$ and rotational constants B_v for Ar_2 are shown, taken from Docken and Schafer (ref. A1). The vibrotor levels $\epsilon_{v,j}$ are given within an accuracy for $\epsilon_{v,j}/k$ of .2 K (ref.A1) by

$$\epsilon_{v,j} = \epsilon_{v,0} + B_v \cdot j \cdot (j+1) \quad (\text{A1.1})$$

Because ^{40}Ar has a nuclear spin $I = 0$, it behaves like a boson and only even values of j are allowed (see ref. A2). For each vibrational level the largest j value, $j_{v,\text{max}}$, for which a bound state occurs ($\epsilon_{v,j} < 0$) is given in column 4. Alternatively, we calculated the $\epsilon_{v,0}$ levels for a Lennard Jones 12-6 (L.J.)

table A1.1

| Ar | | | |
|----|----------------------------|----------------|--------------------|
| v | $-\epsilon_{v,0}/k$ (K) | B_v/k (K) | $j_{v,\text{max}}$ |
| 0 | 120.1 | .083 | 36 |
| 1 | 83.4 | .087 | 32 |
| 2 | 54.4 | .069 | 26 |
| 3 | 32.7 | .062 | 22 |
| 4 | 17.4 | .052 | 16 |
| 5 | 7.8 | .042 | 12 |
| 6 | 2.6 | .030 | 8 |
| 7 | .46 | .017 | 4 |
| 8 | .004 | .003 | 0 |

Table A1.1 Vibrational levels and rotational constants for Ar_2 from ref A1. The well depth $\epsilon/k = 140.8$ K.

interaction potential $V(r) = \epsilon \{ (R_m/r)^{12} - 2(R_m/r)^6 \}$ in first order J.W.K.B. approximation by solving the $\epsilon_{v,0}$ values with $j = 0$ for which v assumes integer values in

$$v + .5 = 2 m_1^{-1} / h \int_{r_1}^{r_2} \left[\epsilon_{v,j} - V(r) - \frac{\hbar^2 j(j+1)}{m_1 r^2} \right] dr \quad (A1.2)$$

Here r_0 and $r_1 > r_0$ are the two zero points of the integrand; m_1 stands for the monomer mass. It is convenient to write eq. A1.2 in a reduced form

$$v + .5 = 2/\Lambda^* \int_{r_1^*}^{r_2^*} \left[\epsilon_{v,j}^* - V^*(r^*) - \frac{\Lambda^{*2} j(j+1)}{4 r^*} \right] dr^* \quad (A1.3)$$

where $r^* = r/R_m$, $r_0^* = r_0/R_m$, $r_1^* = r_1/R_m$, and $\epsilon_{v,j}^* = \epsilon_{v,j}/\epsilon$,

$V^*(r^*) = r^{*12} - 2r^{*6}$. The quantity Λ^* stands for the reduced de Broglie wavelength[†] $\Lambda^* = h/R_m (m_1 \epsilon)^{1/2}$. With $j = 0$ the integral in eq. A1.3 is independent of Λ^* and the $\epsilon_{v,0}$ values depend linearly on $1/\Lambda^*$.

For Ar_2 the reduced $\epsilon_{v,j}^*$ from the L.J. potential with parameters ϵ and R_m of ref. A3, are within 1% equal to the $\epsilon_{v,0}/\epsilon$ values from ref. A1. Therefore, the $\epsilon_{v,0}$ values given in table A1.1 are reproduced by our L.J. approximation if we increase at constant $\Lambda^* = .166$ the well depth ϵ of the L.J. potential, $\epsilon/k = 124$ K, to the one from ref A1, $\epsilon/k = 140.8$ K.

By applying eq. A1.3 one can obtain $\epsilon_{v,j}$ for $j = 0$ too; however, we approximate $\epsilon_{v,j}$ for the L.J. potential according to eq. A1.1 with $B_v = B$ for all vibrational levels. The rotational constant B is taken at the equilibrium distance of the dimer, $B = \hbar^2/m_1 R_m^2$. This approximation yields a value for the partition function Z_2 about 15% too small at maximum.

For ^{20}Ne the vibrational levels $\epsilon_{v,0}$ and rotational constants B_v are displayed in table A1.2 taken from the discussion of Tanaka et al. (ref. A4) of UV absorption measurements and their comparison to differential cross section measurements by Siska et al. (ref. A5).

The interaction potential of $(H_2)_2$ does support only the $j = 0$ and $j = 1$ state, with $v = 0$. The energies $\epsilon_{v,0}$ given in table A1.2 are calculated for a L.J. potential with $\Lambda^* = 1.54$, by directly solving the radial Schrödinger equation for the H_2 dimer (ref. A6).

We calculated the vibrational levels $\epsilon_{v,0}$ for N_2 and NO using eq. A1.3 with $\epsilon/k = 91.5$ K, $R_m = 4.132$ Å, $\Lambda^* = .209$ and $\epsilon/k = 119$ K, $R_m = 3.90$ Å, $\Lambda^* = .188$, respectively. These values for ϵ and R_m are taken from the force constants determined from viscosity data given in ref. A3. Also indicated in table A1.3 are

[†] A definition for Λ^* used by other authors (see e.g. ref. A3) involves the finite zero point of the potential σ , instead of R_m . The resulting value for a L.J. potential is a factor $2^{1/6}$ larger than the one from our definition.

the maximum rotational quantum number $j_{v, \max}$ using a rotational constant $B = \hbar^2/m_I R_m^2$, $B/k = .101\text{ K}$ for N_2 , $B/k = .105\text{ K}$ for NO . In the calculation of the partition function Z_2 the monomer rotational constants B_v are taken from ref. A7, for N_2 $B_v/k = 2.88\text{ K}$ and for NO $B_v/k = 2.44\text{ K}$.

For the mixed dimer NeAr the $\epsilon_{v,0}$ are similarly calculated for a L.J. potential using parameters $\epsilon/k = 65\text{ K}$, $R_m = 3.46\text{ \AA}$, (ref. A8), $\Lambda^* = \hbar/R_m (2\mu\epsilon)^{1/2} = .30$ where μ is the reduced mass. The $\epsilon_{v,0}$ value thus found, could be compared to the levels calculated from a more refined potential (see ref. A9). The small effect found for Ar did not seem to justify this effort.

table A1.2

| ^{20}Ne | | | | H_2 | |
|------------------|----------------------------|----------------|---------------|--------------|----------------------------|
| v | $-\epsilon_{v,0}/k$ (K) | B_v/k (K) | $j_{v, \max}$ | j | $-\epsilon_{0,j}/k$ (K) |
| 0 | 25.3 | .23 | 9 | 0 | 3.7 |

Table A2.1 Relative ionization cross sections at electron energies 100 and 130 eV (column 1 and 2, see ref. A 10). In column 3, 4, and 5 the relative efficiencies are given for ionization gauges from ref. A 12a, b, and c, 5a and 5b correspond to different modern gauges, see ref. A11c

A2 IONIZATION CROSS SECTIONS AND DETECTION EFFICIENCY

In order to compare the monomer intensities for the mixed gases we have tabulated some ionization cross sections with respect to the one of Ar. The electron energies used in the experiment are 100 and 130 eV; in column 1 and 2 of table A2.1 the relative ionization cross sections are given at these two electron energies, taken from ref. A10. At both electron energies the Ar ionization cross section is about 3 \AA^2 (ref. A11). Experimental data on the relative efficiency for some ionization gauges from literature are given in column 3, 4 and 5 (ref. A12).

For noble gas ions Boerboom et al. (ref. A13) have measured the gain of an electron multiplier, similar to the one used in our experiment, at ion energies varying between 3 and 90 keV. They observed the gain to be proportional to $\sqrt{E - \sqrt{E_0}}$, where E is the energy of the ion impinging on the multiplier and E_0 is the ion energy at a velocity of $5.5 \times 10^4 \text{ msec}^{-1}$. In our experiment the ion accelerating voltage is 900 V and the voltage across the multiplier 2 kV. The total ion energy is 2900 V.

Neglecting possible differences in the transmission through the ion optics and the mass magnet, one can calculate the overall relative detection efficiency for Ne compared to Ar from table A2.1 (a relative factor .21) and from the above mentioned multiplier gain (a relative factor 1.26). Our measured ratio of intensity for Ne⁺ and Ar⁺, $I_{\text{Ne}} / I_{\text{Ar}}$, thus indicates that no or very little enhancement of the heavier component occurs in the beam; for a 3:1 mixture Ne-Ar we find $I_{\text{Ne}} / I_{\text{Ar}} = 0.8 - 1.0$, in the onset region.

SAMENVATTING

In dit proefschrift worden resultaten gegeven van een experimenteel onderzoek aan kleine clusters opgebouwd uit eenvoudige atomen en moleculen

Uit gemeten differentiele botsingsdoorsneden en tweede viriaal coëfficiënten zijn paar-potentialen te berekenen voor edelgassen welke in goede overeenstemming zijn met UV absorptie metingen, ook zijn bij hoge drukken IR absorptie spectra gemeten van $(\text{N}_2)_2$, O_2Ar en Ar Recentelijk is de bundel resonantie methode toegepast op dimeren die een elektrisch dipoolmoment ($(\text{HF})_2$, ArHCl , $(\text{H}_2\text{O})_2$, en Ar) of een magnetisch dipool moment (KAr , en Ar) bezitten

Bij alle niet spectroscopische metingen wordt alleen het massaspectrum gebruikt als indicatie voor het optreden van neutrale clusters Fragmentatie bij detectie wordt of klein verondersteld of geheel verwaarloosd De waargenomen intensiteiten worden geïnterpreteerd in termen van een kinetisch of thermodynamisch model voor de vormingsprocessen van kleine clusters

Wij hebben deze assumptie van kleine fragmentatie en de kwantitatieve conclusies betreffende de vormingsprocessen in twijfel getrokken De verzwakking van de neutrale clusterbundel in een verstrooiingskamer moest aantonen of tussen de ionen signalen en bepaalde neutrale clusters een eenduidige correspondentie bestaat Het resultaat is bijna geheel negatief alleen voor dimeren, en dan nog bij zeer lage drukken waarbij het signaal bij de meeste oudere onderzoeken in de buurt van de detectie drempel ligt, kan men de correspondentie vinden

In hoofdstuk II zijn de in 1973 gepubliceerde eerste resultaten gegeven voor een H_2 -cluster bundel Door de aanwezigheid van een ionen ruimtelading in de ionisator is hier het dimeer signaal nog niet geheel zuiver

In hoofdstuk III zijn de metingen gegeven aan een Ar clusterbundel waarbij de ruimtelading door zorgvuldige instelling van de massaspectrometer onderdrukt is De intensiteiten van ionen signalen tot en met Ar_4^+ zijn gegeven Door onze verstrooiingstechniek is duidelijk aangetoond dat een eenduidig verband tussen neutralen en ionen signalen bestaat voor monomeren en dimeren bij drukken lager dan een grenswaarde P_1 Uit de gemeten verzwakking is de botsingsdoorsnede voor Ar_2 bepaald

In hoofdstuk IV zijn resultaten gegeven voor Ne , H_2 , N_2 , NO en O_2 Ook hier zijn de intensiteiten gemeten als functie van brondruk en -temperatuur Voor alle systemen bleek het mogelijk door een reductie van de druk de resultaten voor verschillende temperaturen eenvoudig weer te geven De botsingsdoorsnede is gemeten voor de dimeren ten opzichte van die van monomeren, voor brondrukken lager dan P_L

In par IV 4 is een eenvoudige empirische formule gegeven voor P_1 , uitgedrukt in gereduceerde grootheden, geldig voor de tot nu onderzochte systemen

Uit de afbuiging van dimeren in een inhomogeen magneetveld kon een magnetisch moment vastgesteld worden voor $(\text{H}_2)_2$ en $(\text{O}_2)_2$, echter niet voor $(\text{NO})_2$ (par. IV.5). Voor $(\text{H}_2)_2$ en $(\text{O}_2)_2$ opent dit de mogelijkheid tot bundel resonantie metingen.

In hoofdstuk V geven wij de intensiteiten en verzwakkingen voor een He clusterbundel. Bij lage brondrukken is ook hier een signaal gevonden dat eenduidig toegekend moet worden aan een kleinste cluster, dat hier echter een He trimeer moet zijn.

In hoofdstuk VI gaan we in op de vraag of de dimeren reeds in de bron aanwezig zijn („prefabrication”) of in de expansie gevormd worden („postfabrication”). De dimeerconcentratie blijkt voorspeld te kunnen worden door een evenwichtsberekening gebaseerd op de aanneming van „prefabrication”, binnen een orde van grootte, voor Ar, Ne en H_2 zelfs beter. De brondrukafhankelijkheid voor dimeren van N_2 en NO wijst echter duidelijk op „postfabrication”.

Bundels uit mengsels van gassen zijn beschreven in hoofdstuk VII. Gemengde dimeren NeAr, HeNe en H_2Ar zijn aangetoond en hun botsingsdoorsnede is bepaald.

Tenslotte wordt in hoofdstuk VIII een overzicht gegeven van alle gemeten dimeer botsingsdoorsnedes σ_2 t.o.v. die van de monomeren σ_1 . Alle σ_2/σ_1 verhoudingen blijken op een universele kromme te liggen, wanneer uitgezet als functie van een gereduceerde snelheid

Bij lage gereduceerde snelheden is $\sigma_2/\sigma_1 \simeq 1.4$, bij hoge snelheden $\sigma_2/\sigma_1 \simeq 2$. De verhouding σ_2/σ_1 bij lage gereduceerde snelheden kan verklaard worden uit een C_6 constante voor de dimeren, ongeveer 2.3 maal groter dan die van de monomeren.

Bij hoge gereduceerde snelheden komt de gemeten verhouding $\sigma_2/\sigma_1 = 2$ overeen met de verwachting voor een los gebonden dimeer, waarin de bouwstenen als onafhankelijke botsingspartners beschouwd kunnen worden; bij botsingen met hoge snelheden is hun actieradius vergelijkbaar met of kleiner dan hun onderlinge afstand.

CURRICULUM VITAE

Op verzoek van het college van dekanen volgt hier een kort overzicht van mijn studie.

In 1965 behaalde ik het diploma gymnasium- β aan het St.-Thomascollege te Venlo en begon mijn studie natuurkunde aan de Katholieke Universiteit te Nijmegen. Het kandidaatsexamen werd afgelegd in 1968, het doctoraal examen experimentele natuurkunde volgde in 1971. Een afstudeerstage bij de werkgroep Atoom- en Molecuul fysica, onder leiding van Prof. Dr. A. Dymanus en Dr. J. Reuss ving aan in 1969. Na het doctoraal examen ben ik, in dienst van de stichting Fundamenteel Onderzoek der Materie, aan voornoemde afdeling verbonden als wetenschappelijk medewerker ter voorbereiding van dit proefschrift, onder leiding van Dr. J. Reuss.

Na het kandidaatsexamen en ook tijdens het promotie-onderzoek ben ik als assistent werkzaam geweest bij verscheidene werkcolleges alsmede bij het practicum natuurkunde.

Errata

In eq. VI.4 please read $G(kT/\epsilon)$ instead of $G(Tk_0/\epsilon)$, in eq. VI.6 $G(kT_0/\epsilon)$ instead of $G(Tk_0/\epsilon)$.

Eq. A1.2 should be read

$$v + .5 = \frac{2m_1^{1/2}}{h} \int_{r_0}^{r_1} [\epsilon_{v,j} - V(r) - \frac{\hbar^2 j \cdot (j+1)}{m_1 r^2}]^{1/2} dr .$$

eq. A1.3

$$v + .5 = 2/\Lambda^* \int_{r_0^*}^{r_1^*} [\epsilon_{v,j}^* - V^*(r^*) - \frac{\Lambda^{*2} j \cdot (j+1)}{4\pi^2 r^{*2}}]^{1/2} dr^*$$

on the second line below eq. A1.3 $V^*(r^*) = r^{*-12} - 2r^{*-6}$.

I

Vanwege de grote discrepantie tussen de botsingsdoorsnede voor rotatie-aanslag van H_2 , berekend met verschillende op het moment bekende anisotropie parameters, is het aan te bevelen deze botsingsdoorsnede in een onafhankelijk experiment te bepalen.
